*" To the solid ground
Of Nature trusts the mind which builds for aye."*—WORDSWORTH.

THURSDAY, NOVEMBER 1, 1900.

A NEW FRENCH FORESTRY TEXT-BOOK.

Les Forêts. Par L. Boppe, Directeur honoraire de l'Ecole Nationale des Eaux et Forêts de Nancy, et Ant. Jolyet, chargé de cours à l'Ecole. Pp. xi. + 488. (Paris: J. B. Baillère et Fils, 1901).

WITHIN the last ten years the course of instruction at Nancy has been considerably modified. The school is attended by some foreign students, who, as well as a few occasional private French students, are admitted without any regular examination. Formerly, students intended for service in the State and Communal forests of France passed a preliminary competitive examination in the subjects usually taught at a Lycée, including physics and chemistry. A knowledge of botany, entomology and geology, however, was not required of them, these subjects being taught *ab initio* at Nancy; in those days the marks obtained for forestry unduly overshadowed those given for natural history, and only a few devoted naturalists were to be found among French forest officers. Forestry teaching at Nancy also was much too dogmatic, and not sufficiently based on experimental results.

At present, French forest students who are intended for the service of the State come from the *Institut National agronomique*, and must obtain a diploma there before being admitted to Nancy. About eighty students enter the Institut agronomique annually, while the number of State students at Nancy is limited to twelve per annum, the last twelve men admitted to Nancy standing 1, 3, 6, 7, 9, 10, 15, 21, 24, 26, 39 and 48 at the final examination of the Institut agronomique. Nancy students thus at present possess a considerable knowledge of agriculture and experimental natural science; they also get pecuniary allowances from the State, so that admission to the French forest service is open to a wide field of French citizens, and is not confined, as are some of our own public departments, to a restricted class of men, who have sufficient means to pay the high cost of training involved, this restriction injuriously affecting the intellectual standard of the departments.

Forestry teaching at Nancy has responded admirably to the higher attainments of the present class of students, and it is a real pleasure for one who studied there nearly thirty years ago to note the excellence of this new text-book of sylviculture.

In it a forest is described as a complex organic whole, composed of a porous and friable humous soil, covered with dead leaves and moss, wherever the shade is too great for vegetation other than saprophytes; where, however, the mature crop of trees has been thinned or cleared with a view to natural regeneration, the soil is soon overgrown with grasses or other herbaceous plants, as well as brambles, bushes and shrubs, which, together with the young plants of the valuable forest species, form a complex mass from which saplings, poles and trees gradually emerge, and compose a new crop, either as coppice or high forest. This evolution of a new crop from an old one requires considerable skill on the part of a forester, and it is only by carefully observing and following nature that success is obtained. Each forest species makes different demands on soil and climate and requires in its young state various degrees of protection against hostile meteoric influences, injurious plants and animals.

In France natural regeneration, either by seed or by coppice shoots, is the chief means of reproducing a forest, and human interference with the growing forces of nature is reduced to a minimum. The chief classes of French indigenous high forests, reproduced by seed, consist of oak, beech or silver-fir; maritime pine in Gascony; larch and spruce in the Alps, the latter also growing in the Jura with beech and silver fir; *Pinus sylvestris* (for which our name of Scotch pine is far too local, and as a substitute for which I would suggest the name red pine) is indigenous in France only in mountainous regions, but has been extensively planted on poor sandy soils in the lowlands. There are extensive coppices of mixed underwood with oak and other standards, and of holm oak with Aleppo pine standards, in Provence. The holm oak (*Quercus Ilex*) prefers calcareous soils, and is replaced in the south of France, on siliceous soils, by the two very valuable cork oaks (*Quercus Suber* and *Q. occidentalis*), the latter differing from the former by its habitat near the Bay of Biscay, and by its taking two years to mature its

acorns. Both these oaks are usually grown isolated in vineyards for their cork. *Quercus Tozza* is restricted to the south-west of France, where extensive coppices of it are grown for fuel. Hornbeam is abundant in the north-east, chiefly in coppice-with-standards; its abundance in Epping Forest probably dates from the time when England was connected by land with the Continent. Other species of forest trees, such as ash, alder, sweet-chestnut, sycamore, willows, poplars, birch, lime, elms, &c., are either confined to special soils over small areas, or disseminated in forests of the principal species that have been already mentioned. Maps are given in the text-book showing the geographical distribution of the principal trees.

There is an excellent chapter on the action of trees on one another, and on the value of shade-bearing species, such as beech, as auxiliaries to the more valuable light-demanding trees, such as the pedunculate and sessile oaks, the former being chiefly grown in the lowlands on deep, moist or even wet soils, as standards over coppice, and the latter with beech in high forests on the hills. Both these oaks, as well as the holm oak, are also extensively grown in coppice woods, chiefly for their bark, as tanning material.

A good account is given of the nature of forest soil, and the necessity of preserving the dead leaves to form humus is strongly insisted on. It has been proved by Grandeau and Henry, two of the Nancy professors, that besides serving as food for earthworms and other organisms, the activity of which keeps the soil porous, friable and superficially rich in nutritive mineral matter, dead leaves fix atmospheric nitrogen to the extent of 12–20 lbs. per acre annually. To deprive the forest of its dead leaves is like robbing a farm of its dung.

The evolution of a crop of trees by natural regeneration is well described, the account of coppice-with-standards being probably more complete than in any other text-book. The cultural methods to be followed when once the new crop is established are also well explained and chiefly consist of cleanings and thinnings. The authors are strongly opposed to the pruning of forest trees, and consider that drainage is very rarely required. Their remarks on these points should be read. Among sylvicultural systems yielding even-aged high forest (*futaie regulière*), the clear-cutting system (*procédé par coupe unique*), which is so extensively followed in parts of Germany for crops of spruce or red pine, is employed in France only for maritime and Aleppo pines. The cones of the pine trees adjoining a clearing produce abundance of seed, which at once stock the ground, provided the felled material is rapidly removed, and the seedlings of these trees are so vigorous and hardy against drought, that they soon dominate the mass of bushes and weeds springing up around them.

The system under which a mature crop is gradually removed (*procédé par coupe successive*), termed by Dr. Schlich shelter-wood compartment system, is that commonly employed in French high forests. It gives admirable results in oak and beech woods, but its application to silver-fir is not so successful, as silver-fir grows better when the larger trees are surrounded by an irregular undergrowth of beech and silver-fir.

The selection system (*jardinage*) similar to that employed in the Chiltern Hills for beech, is much used in France for silver-fir, chiefly in communal and private forests, and in State forests in mountainous districts, where it affords the best protection against denudation of the slopes.

About 70 pages of the book are devoted to an accoun of possible injuries to the forest by men, animals, plants and meteoric influences. This really constitutes the subject of Forest Protection, and is usually dealt with apart from sylviculture in German and English forestry text-books. One hundred and sixty pages at the end of the book treats of artificial reproduction, and resemble the account of sowing and planting usually given in other good sylvicultural works. This part of the book terminates with an account of exotic trees, the introduction of which is not viewed in France with nearly so much interest as with us, although the subject is very judiciously treated in the present volume.

The book is profusely illustrated by reproductions of photographs chiefly taken by Nancy students during their summer tour; it forms a highly valuable contribution to forestry literature, and is certainly the best account of French sylviculture that has yet appeared. There is a good table of contents, but no index, the omission of which is to be regretted. W. R. FISHER.

TOPOGRAPHIC SURVEYING.

Topographic Surveying. By Herbert M. Wilson. Pp. 884. (New York: Wiley and Sons. London: Chapman and Hall, 1900.)

MR. WILSON'S book is comprehensive, clear and well illustrated, and contains much information of practical use to the surveyor and explorer, which is not usually found in works on surveying and map-making. Its author is a member of the staff of the United States Geological Survey, and his remarks on the methods and processes of that Survey are therefore of special interest.

The Geological—which is virtually a topographical—Survey of the United States is a work of great magnitude, and the manner in which the staff engaged upon it have met the numerous technical, transport and other difficulties that have arisen during its progress is most interesting. It was laid down as a general principle that no part of the country should be surveyed in greater detail, or at greater cost, than was necessary for the purposes which the resultant map was intended to subserve. This involved a rapid and economical survey of a vast extent of country within reasonable limits of error. The method adopted

"consists of a combination of trigonometric, traverse and hypsometric surveying to supply the controlling skeleton, supplemented by the 'sketching in' of contour lines and details by a trained topographer. In this method the contour lines are never actually run out, nor is the country actually cross-sectioned."

The instruments used vary with the nature of the country. For geodetic work, a combination transit and zenith telescope of special pattern (p. 726) has been found most convenient. Primary bases are measured with steel tapes, with an average probable error of 1/300,000, in from seven to ten days, at a cost of 20*l*. to 40*l*.; whilst the bases of the U.S. Coast and Geodetical Survey have

a probable error of 1/1,000,000 to 1/1,500,000, take from two to six months to measure, and cost from 500*l.* to 2600*l.* The observations for the primary triangulation are made with an 8-inch direction theodolite, the average rate and cost being six stations per month and 3*s.* 7*d.* per square mile, and the average probable error of the triangulation 1/40,000. The averages of the Geodetic Survey are three-fourths of a station per month, from £2 to £6 per square mile and the probable error 1/150,000. For filling in the detail the essential instruments are the plane-table and telescopic alidade (p. 156). The horizontal distances are obtained, according to circumstances, by triangulation with the plane-table, by stadia and odometer measurements, by chaining, and by pacing. The altitudes are dependent upon primary lines of levels run with a precise spirit-level (p. 328), and having a probable error in feet $= \cdot 02 \sqrt{\text{distance in miles}}$; on angles of elevation and depression at the principal trigonometrical stations, on secondary lines of spirit-levels and on aneroid observations. The topographical features are represented on the map by contour lines sketched by eye with the assistance of an aneroid, and great importance is attached to the quality of the sketching. This depends upon the artistic and practical skill of the topographer, or upon his ability to make correct generalisations, and decide upon the amount of detail which should be omitted or preserved so as to bring out, on the selected scale, the predominant features of the country surveyed. In this work, as the author justly remarks, great proficiency "can only be attained after years of experience." He also rightly holds that the topographer should have a sufficient knowledge of geology and physiography, or of the "origin and development of topographic forms," to enable him to appreciate the features which he is sketching and to represent them intelligently on his sketch.

Mr. Wilson's book is, however, very far from being a simple manual for the use of the Geological Survey. It deals with every description of survey, and treats each fully. Part i. contains much useful information on the different classes of survey. An interesting description is given of the survey of Baltimore on a scale of 1/2400, which corresponds nearly to the 25-inch scale of the Ordnance Survey; but if the figures given in the table, p. 107 (Baltimore 814*l.* per square mile, Ordnance Survey 59*l.*), are correct, the cost would be considered prohibitive in this country. The remarks on geographic and exploratory surveys are good, and Mr. Johnson's excellent plane-table sketch, which is given as a specimen of an exploratory survey (p. 91), may well serve as a model for sketchers. Military surveys are correctly defined as having for their object "the representation of the natural and artificial features of the country with the maximum exactitude consistent with the greatest rapidity of execution." The concluding chapter is a well illustrated memoir on the relations of geology to topography, and on 'earth sculpture,' or the constructive and destructive processes by which existing topographical features have been formed. The importance of a knowledge of these subjects to the topographer and cartographer is clearly pointed out. A valuable addition to the chapter is a glossary of all geographical and topographical descriptive terms in common use in the United States, which, pending the compilation of a similar list for the United Kingdom, will be found useful in this country.

In Part ii. the instruments and methods employed in the measurement of horizontal distances and in plane surveying are clearly described and explained. Chapters vii. and viii. on plane-tables and alidades, and chapters xii. and xiii. on stadia and angular tachymetry, deserve the attention of surveyors in England, where stadia measurements, which give results over rough ground as good as those with the chain, are little known. In another chapter the author describes photo-surveying methods, which are much in favour in Canada, and points out their limitations and the conditions under which they can be advantageously employed. Part iii. deals with instruments and methods for the determination of altitudes. The American spirit levels and levelling staves are of better pattern than those in use on our Ordnance Survey, and the accuracy of the principal lines of levels is greater than that of the similar lines in Great Britain. In Part iv. the author explains the various kinds of map projections, the methods of representing hill features and the construction of relief maps. He very rightly lays down that the cartographer should be "possessed of such actual knowledge of map-making as is only gained by practical experience in field-surveying," and that the topographer should have a general knowledge of projections and map construction. The difference between the principal methods of representing ground is well brought out; that by hachures is happily characterised as "a graphic system with a conventional element," and that by contours at close intervals as "a conventional system with a graphic element." Wax and clay mixed with glycerine are considered the best materials for modelling, and it is pointed out that a modeller should have a good knowledge of topography. Parts v. and vi., "Terrestrial Geodesy" and "Geodetic Astronomy," are clearly written and well supplied with tables; and the latter contains a chapter on "Photographic Longitudes." In Part vii. the surveyor in unsettled country will find many excellent hints as to camp stores and equipment, pack transport, medicines, clothing and photography.

In conclusion, it may be added that the book contains 884 pages, 62 tables of various kinds, 205 excellent illustrations, and a most useful index. It would in some respects have been more convenient if it had been published in two volumes. C. W. W.

THE ETHNOGRAPHY OF BRITISH COLUMBIA.

Memoirs of the American Museum of Natural History. Vol. II. *Anthropology.* i. *The Jesup North Pacific Expedition.* iv. *The Thompson Indians of British Columbia.* By James Teit. Edited by Franz Boas. (1900.)

IMPORTANT results were looked for from the Jesup North Pacific Expedition, and the realisation has not belied the expectation. Thanks to the intimate knowledge of Mr. James Teit of their language, customs and beliefs, we now have a remarkably detailed and complete description of the Upper and Lower Thompson

Indians, especially as this is supplemented by the valuable work done by Dr. G. M. Dawson, Dr. Franz Boas, Mr. C. Hill Tout, and others on these or allied tribes of British Columbia, under the auspices of the British Association for the Advancement of Science.

The Upper Thompson Indians live in the valley of the Thompson River, while the Lower Thompson Indians dwell on the Fraser River. They appear to have decreased to one-third since the advent of the white man in 1858. The birth-rate is about equal to the deaths, but there is great mortality among young children; at the present time the population in some places seems to be about stationary, or is slowly increasing. The Lower Thompson Indians are quieter and steadier than the people of the upper division, but are slower and less energetic; they are also better fishermen and more expert in handling canoes, while the Upper Thompson Indians are better horsemen.

In this copiously-illustrated memoir Mr. Teit has carefully described the handicrafts of the Thompson Indians. Most of their implements were made of stone, bone, wood, bark, skins, matting or basketry. Work in stone, bone and wood was done by the men, while the preparation of skins, matting and basketry work fell to the share of the women. There was a certain amount of division of labour, as workmen skilful in any particular line of work exchanged their manufactures for other commodities.

The various kinds of habitations and clothing and ornaments are fully described, and the changes that have ensued since 1858 are recorded. For example, beads and dyed porcupine quills were largely used for embroidery before that date; but these were soon replaced by embroidery done in silk thread, and most of the patterns wrought at the present day are copies of the white man's patterns. Full accounts are given of the arts, of subsistence, varieties and preparation of food, hunting, fishing and the like, as well as of travel, transportation, trade and warfare.

The games and pastimes of adults and children are carefully dealt with, and this account usefully supplements what has been previously recorded for similar tribes. It is a pity that the author describes as a "bull-roarer" quite another kind of toy, which Culin calls a buzz; the latter is an oblong or circular piece of thin wood, with two holes near the centre through which a string is passed. It is widely distributed among the Indians of North America, and, so far as is known, has little in common with the true bull-roarer. The smaller boys and girls play "cats' cradle," and we are told they make many forms such as the "beaver," "deer," "man stealing wood," &c. Fig. 270 illustrates two of these puzzles, one—"dressing a skin"—is very difficult to follow; the second—"pitching a tent"—is simpler, and, strangely enough, is precisely similar to the "fish-spear" string puzzle of the Torres Straits Islanders.

Very interesting and instructive are the accounts given of the social organisation and festivals of the people, and of the customs relating to birth, childhood, puberty, marriage and death. Their religion is fully dealt with, and it is worthy of note that no totemism is recorded for these people; but each individual has a guardian spirit, which was acquired during the puberty ceremonials. Only a few shamans inherited their guardian spirits without such ceremony from their parents, who had been particularly powerful. The guardian spirits of these parents appeared to them, uncalled for, in dreams and visions. The moral code is excellent, and the young people are often admonished and advised. It is good to be pure, cleanly, honest, truthful, brave, friendly, hospitable, energetic, bold, virtuous, liberal, kind-hearted to friends, diligent, independent, modest, affable, social, charitable, religious or worshipful, warlike, honourable, stout-hearted, grateful, faithful and revengeful to enemies. Various legends are noted, and there are the usual constellation myths; but several of the stars or constellations have not been identified, so that no comparative study is possible. The traditions have been published in full by Mr. Teit in the *Memoirs of the American Folk-lore Society*, vol. iv.

The memoir concludes with a chapter on art and a summary, both by Dr. Boas. The decorative art of the Thompson Indian is very crude; form and decoration have no intimate connection, comparatively few designs are primarily decorative, their fundamental idea being symbolic. For this reason, by far the greater number of designs may be described as pictographs rather than as decorations.

The Thompson Indians are in appearance and culture a plateau tribe, influenced, however, to a great extent by their eastern neighbours, to a less extent by the tribes of the coast. Their whole social organisation is very simple, and the range of their religious ideas and rites is remarkably limited when compared with those of other American tribes. This may be one of the reasons why, in contact with other tribes, the Salish have always proved to be a receptive race, quick to adopt foreign modes of life and thought, and that their own influence has been comparatively small.

If all the field-work done by the numerous investigators on the staff of the Jesup North Pacific Expedition is as complete and workmanlike as the present memoir, and is published in similar first-class style, the result will be a dignified monument to the ability of American anthropologists and to the enlightened munificence of Dr. Jesup.

ALFRED C. HADDON.

OUR BOOK SHELF.

Lubrication and Lubricants. By L. Archbutt and R. M. Deeley. Pp. xxiv + 451. (London: C. Griffin and Co., Ltd., 1900.)

MESSRS. ARCHBUTT AND DEELEY have, in this treatise, placed before engineers and power users what is known of the theory and practise of lubrication.

Until the introduction of mineral oils as lubricants, there was comparatively little difficulty in obtaining good oils; the animal oils, such as sperm and lard, and the vegetable oils, such as castor, will keep a bearing cool, while mineral oils of the same apparent viscosity will allow it to heat. Oil users can only meet this difficulty by subjecting the oil to both chemical and mechanical tests.

The work is divided into two portions: the first treating of the theory of friction and the properties of lubricating substances, while the second describes the forms of bearings. The experiments of Mr. Beaucamp Towers and

Prof. Goodman have greatly added to our knowledge of the friction of bearings, as distinguished from the friction of rest, as found in our academic text-books. Messrs. Archbutt and Deeley have given a clear and extensive account of the modern ideas on friction.

Prof. Osborne Reynolds' monograph on the theory of friction is certainly one of the finest works on the subject, and it is to be regretted that his results are not more generally known to engineers.

The portion of the present volume relating to the chemical and physical examination of oils is thorough and copious; it will be of great service to chemists, but is somewhat beyond the range of most engineers, who, if they test their oils in any way, use the mechanical oil-testing machine, which, while useful in its way, does not give the same knowledge of the properties of a lubricating oil as does the chemical test.

We consider that oil-testing machines are only capable of yielding satisfactory results in the hands of experts, and then only when much time is expended in experiments. For research purposes they are most admirable, and from their use we have obtained practically all we know of friction; but for commercial testing we should prefer to rely on chemical and physical methods. The design and care of bearings are well described in the second part; all forms of bearings, from those of watches and clocks, cycles and large engines, are illustrated. We are pleased to see the block packings for piston rods described; the ordinary gland packing is certainly a defective form, and is the cause of considerable loss of power, even when no serious heating occurs. The omission of the system of forced lubrication seems a pity, especially as Messrs. Belliss and Morcom have applied it with so much success to their well-known quick-revolution engine. The work is, we consider, of the greatest value, and should be in the hands of both designers and users of all forms of machinery in which lubrication is important. F. W. B.

Darwin and Darwinism, Pure and Mixed. By Dr. P. Y. Alexander. Pp. xii + 346. (London: Bale, 1899.)

THE decade which followed the appearance of the "Origin of Species" witnessed the publication of innumerable books and articles dealing with Darwin's great work. Although many of these were solid and valuable contributions to the literature of evolution and natural selection, the mass as a whole was characterised by the large proportion of works which proclaimed with the utmost confidence the opinions of authors unknown as naturalists. Men whose claim to a hearing was of the slenderest kind spoke with contempt of Darwin's reasoning powers or the rashness of his generalisations. After 1870 such works became rarer, and at the present day are, happily, quite uncommon. The book before us is, however, about as bad an example as can be found. It would not have been astonishing in 1869 to be told by a writer unknown as an original observer or thinker that "Mr. Darwin's capacities of thinking and drawing inferences from the immense masses of fact he had collected were not at all equal to his powers of observation, investigation and classification," or to observe the calm satisfaction in the following sentence: "My little effort will show that, wherever I have paid special attention to any department of natural history or natural science, I am apt to find Mr. Darwin at fault, more especially in his generalisations." The mildest statement which can be made about the publication thirty years later of such opinions by a Mr. P. Y. Alexander—author of "Heredity," "Parasitism," &c., notwithstanding—is that the work is an anachronism.

The literary style may be sufficiently exemplified by a couple of quotations from the "Argument of the Book."

"(2) Mr. Darwin went for essential *slowness* as a necessity of nature. He said in 'Origin' 'Nature can never take any great and sudden leaps.' When instances were presented to him of 'sudden leaps,' he tried to gloss it over, and always harked back on *slowness*" (p. ix.).

"(7) Mr. Darwin's notion that 'domestic animals which have long been habituated to a regular and copious supply of food *without* the labour of searching for it are more fertile than the corresponding wild animals,' shown by instance on instance to be *absurd*, opposed to the practice of all great breeders, and is, besides, physiologically impossible" (p. xi.).

It is probable that the reader who looks at such sentences as these will not feel sufficiently encouraged by the manner or matter to penetrate further, even though "the most absolute refutation of poor Darwin's fallacy" should be later on established, to the entire satisfaction of the author. E. B. P.

Electric Wiring Tables. W. P. Maycock. Pp. iv + 144. (London: Whittaker and Co., 1900.)

MR. MAYCOCK'S pocket-book of tables should prove very useful to those electrical engineers whose work consists solely of wiring and fitting. It contains in a very convenient form tables of all the quantities likely to be wanted in such work, and has the advantage of being quite up to date, the values in the tables of the safe currents, resistances, &c., of copper conductors being calculated on the basis of the recommendations of the Institution of Electrical Engineers Committee on Copper Conductors, which only made its report at the beginning of this year. It is, perhaps, a disadvantage of the pocket-book that it is so limited in its scope, and we are inclined to think that it would appeal more strongly to the particular class of electrical engineers for which it is designed if more general information were included. A summary of the fire insurance rules should certainly be inserted, and it would be useful if some idea were given of the approximate costs of wiring on the different systems alluded to in the section on "Systems of Wiring." Some of the tables are simply "Ready Reckoners"; for example, the tables of "Price and Length of Conductors" give the prices of different lengths of conductors calculated from the price per yard, and would apply equally well to wood-casing and metal-piping, a fact which should be indicated in the title of the table. The table giving the current taken by different numbers of lamps working at different pressures and different efficiencies is a very useful one, particularly now that high-efficiency lamps are being brought forward. The same can hardly be said of the list of towns supplying on the alternate current system, since no details are given as to pressure and frequency. The usefulness of the pocket-book would be considerably increased by the addition of an index.

Raggylug, the Cottontail Rabbit; and other Animal Stories. By Ernest Seton-Thompson. Pp. 147. (London: David Nutt, 1900.)

MR. SETON-THOMPSON'S success as a writer about animal life lies in the fact that he endows his subjects with human faculties and sympathies. It is, of course, illogical to make animals consider everything from an anthropomorphic point of view; but, after all, this is the only point of view which it is possible for us to conceive, and there is no objection to occupying it, provided that its artificial nature is borne in mind. By following this method, Mr. Seton-Thompson's animal stories have a sentimental interest, and they create a love of animate nature in the minds of all who read them. There are four stories in the present volume, and each is an instructive as well as interesting narrative of animal life. Children will read the stories with delight, and adults will find their sympathies awakened by them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Leonids—a Forecast.

IN the *Proceedings* of the Royal Society for March 2, 1899 (vol. lxiv. p. 403), will be found an account of the perturbations suffered since 1866, November 13, by the Leonids which in that month intersected or passed close to the earth's orbit. This position in the meteor stream may be called station A (Fig. 1).

We have since investigated the principal perturbations affecting two other points in the stream, viz., the station Z, which intersected the earth's orbit 360 days earlier, *i.e.* in November

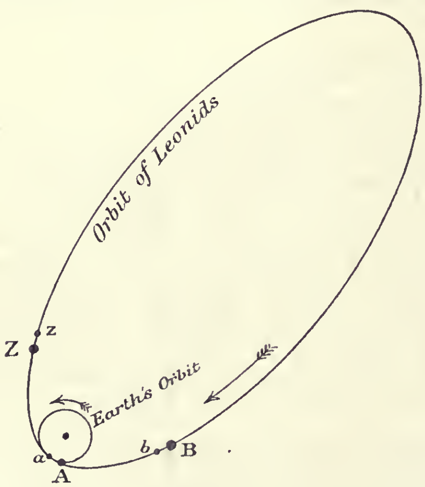

FIG. 1.

1865, and the station B, which intersected the earth's orbit 360 days later, *i.e.* in November 1867.

We therefore now know the principal perturbations which during the last revolution of the meteors have affected three points, Z, A and B, situated along an orbit (Adams's orbit) which, at the commencement of the revolution, lay within the stream.

The full results of the investigation will not be ready for publication till after the time when the Leonid shower of this year is due, and on this account it has been thought expedient

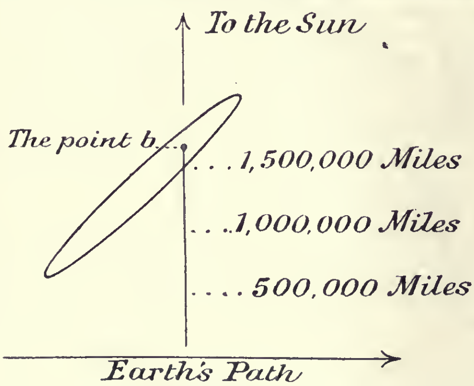

FIG. 2.

to publish beforehand such of the results as have special reference to it.

A point in the stream which in 1867 lay along Adams's orbit between A and B, but nearer B, and which we may call the point *b*, will this year reach its descending node simultaneously with the earth. This will happen approximately on 1900, November, 15d. 3h. Greenwich mean astronomical time.

Unfortunately, the orbit of a meteor situated near point *b* in the stream, instead of intersecting the earth's orbit as it did in 1867, will now pierce the plane of the ecliptic in a point which lies about 0·018 nearer the sun. Now, 0·018 of the earth's mean distance from the sun is 1,674,000 miles; so that, of the meteors which in 1867 intersected the earth's orbit, those which will come nearest to the earth in the present year will not approach it nearer than a million and six hundred thousand miles.

It is known from the duration of the great showers that the width of the ortho-stream, if measured in the direction which is parallel to the earth's path, is only about 300,000 miles; but there is reason to believe that the Leonids entered the solar system under conditions which have made the section of the stream much longer than it is broad, so that its trace upon the plane of the ecliptic is something like what is represented in Fig. 2. The longer axis of this cross section lay originally along the radius vector from the sun, but perturbations have acted on the Leonids for nearly 1800 years of such a kind as have probably caused the section of the stream to incline in the direction represented in the figure.

If the section is long enough to reach the earth's orbit, we shall have a great meteoric shower this year. It is, besides, just possible that a sinuosity in the stream may so displace a part of the section as to bring it sufficiently far out. But neither of these seem likely to have happened; so that the present investigation does not raise any hope of a great shower this year.

If, contrary to our expectation, the axis major of the section proves to be long enough to reach the earth's orbit, the consequent shower of ortho-Leonids is likely to occur several hours—possibly more than a whole day—earlier than

1900, November, 15d. 3h.

The number of hours by which it will precede that epoch depends upon the angle which the axis major of the section makes with the radius vector from the sun—an angle which is at present unknown. If there is this year a shower of ortho-Leonids, the time at which it occurs will enable us to determine this important datum.

Station *a* in the stream (see Fig. 1) intersected the earth's orbit in 1866, but after completing a revolution it passed the earth in November of last year at a distance of some 1,300,000 miles; and *z*, the corresponding point for the preceding year, which also intersected the earth's orbit in 1865, was on its return distant from the earth in November 1898 by about 960,000 miles. It thus appears that the displacements of the meteoric orbits which have been brought about by the perturbations of the last thirty-three years suffice to have prevented the meteoric orbit from now intersecting the earth's orbit. This accounts for our not having had any great shower in either of the last two years, and unfortunately the conditions seem still more unfavourable in the present year.

Nevertheless, as there is always a possibility that one or other of the contingencies mentioned above may carry a part of the ortho-stream out as far as the earth, and as we have no means of ascertaining whether those contingencies have arisen, it is desirable that preparation shall be made for adequately observing the shower, if it should unexpectedly come.

The perturbations during the last revolution, which have for the present carried the ortho-stream of Leonids so far from the earth's orbit, belong to the class of perturbations which act at different times with equal effect in opposite directions; so that there is reasonable ground for expecting that further perturbations must at some future time bring this remarkable stream back to the earth's orbit. It would be possible to ascertain when this will happen, by an investigation carried over a sufficient time forward upon the same lines as those which we have pursued.

October 24.

Examinations in Experimental Science.

YOU occasionally do us, who are humble teachers of Elementary Science in schools, the very great kindness of giving us, through your columns, the chance of reaching the ears of those eminent men who are your frequent contributors, and who examine our pupils. Will you, in the interest of that real science teaching, so often advocated in your columns, allow me such a chance now? I will be as brief as possible. In common with a few individuals and many public bodies, I have spent a very large amount of time, money and labour in introducing the teaching of practical physics into my school, and trying to see that it shall be of the best kind possible, and I am prepared to do more.

But really there must be some agreement between us and the said eminent men as to what practical science is when the examination paper is composed.

May I give my illustration? The Cambridge Local Syndicate have introduced Elementary Experimental Science, three papers, into their junior syllabus. The other day I set two of these three papers for 1899 to a number of boys who had had a most careful experimental training in the matter of the syllabus. They made wry faces over it, and were heard to remark afterwards that they did not see what it had to do with the experiments they had been doing. On marking the papers I found that the best boys, really very good and careful experimenters and observers and good draughtsmen, for boys, barely reached forty per cent. of the marks. The same papers were set to a sharp boy of the same age who had done no experiments, but had been through the same subjects, mechanics, hydrostatics, and heat, in the old way, viz., text-book and problems. *He scored nearly full marks on all the physics questions.*

The fact is, that except for the heading, "Experimental Science," there is nothing in two of these papers to indicate that they are set to candidates whose knowledge is based on and drawn from experimental work of their own.

I should like to ask you to print these papers in full, that the eminent men who set them might have a chance of saying something, but on the whole I think your space is too valuable. I will simply quote two questions from the mechanics paper.

"(3) Explain how work is measured, and in what units.

"A 50 lb. shot is fired from a cannon with a velocity of 1500 feet per second. Compare the work done on the shot with that done by a man weighing 12 stone who walks up a hill 1500 feet high.

"(4) What is the mechanical advantage of a machine?

"How would you arrange three separate pulleys, each of which weighs 1 lb., so that the power required to raise a weight of 40 lbs. may be a minimum?

"What arrangement of pulleys is most commonly used in practice? And why?"

Now these are exactly the old Cambridge—"Describe the common pump, &c., questions?" and the way to answer them is to waste no time on experiments, but read your text-book, get up your formulæ and work examples. The second question is of exactly the same type. The other two require a graphical construction, but such as would be readily done by a boy who had used a text-book in which graphic methods were explained.

The first paper is almost equally bad; it is all (chemistry included) text-book science of a very common order. Against the practical paper I have nothing to say.

Now Cambridge men can write excellent elementary text-books on these subjects, witness those of Prof. Glazebrook. Can they not produce among them a paper on Elementary Experimental Science, which shall be what it professes to be, or is the tradition of the common pump still too strong, and the impress of the Mathematical Tripos too indelible?

A. H. F.

Literature of Coffee and Tobacco Planting.

IN the issue of NATURE of August 9 it is stated, in reviewing a book by a French author, that several books on the same subject, *i.e.* coffee—its growth, cultivation and preparation for the market—have already been published in English.

Could you kindly inform me of the names of the publishers or authors of any good works in English on coffee and tobacco growing? I have been, so far, quite unable, out here, to find the names of any publishers of works on tobacco or coffee, and as it is a matter of considerable moment to me to gain the best of information on these subjects, I trust you will see your way to help me.

Salisbury, Rhodesia, South Africa. G. H. JAMES.

[Mr. J. R. Jackson, Keeper of Museums at the Royal Gardens, Kew, to whom we referred our correspondent's inquiry, has kindly sent the following list of books, which may meet the requirements and also be of service to other planters. —Ed. NATURE.]

WORKS ON COFFEE AND TOBACCO PLANTING.

"The Coffee Planter of Ceylon," by William Sabonadière. Published by E. and F. N. Spon, 125, Strand. (1870.)

"Coffee Planting in Southern India and Ceylon," by E. C. P. Hull. E. and F. N. Spon. (1877.)

Article on coffee in "Spon's Encyclopædia of the Industrial Arts, Manufactures and Commercial Products." E. and F. N. Spon.

"Liberian Coffee in Ceylon." From the *Ceylon Observer*. Published at Colombo by A. M. and F. Ferguson. (1878.)

"All About Tobacco." Compiled by A. M. and F. Ferguson, Colombo, Ceylon. Agents, John Haddon and Co., Bouverie Street, London.

Article on tobacco in "Spon's Encyclopædia of the Industrial Arts, Manufactures and Commercial Products." E. and F. N. Spon.

Autotomic Curves.

IN NATURE, October 11, Mr. A. B. Basset justly inveighs against the use of the term "non-singular curve" to denote a curve which has no double points. Doubtless, also, the expression "an anautotomic curve" is objectionable.

May I suggest that, in this instance, we may obtain from Latin the help unknown to Greek, and designate curves which have, and curves which have not, double points, by the terms *sesecting* and *non-sesecting* respectively?

H. LANGHORNE ORCHARD.

44 Denning Road, Hampstead, N.W., October 20.

IN answer to your correspondent, Mr. A. B. Basset, would not the Anglo-Saxon negative prefix "un" combine more euphoniously with "autotomic" than the Greek "an"? We find analogy for such a combination in the familiar words "unauthorised" and "unauthenticated," where it is used in conjunction with words of Latin origin; so there seems no valid philological objection to its association with a Greek derivative, while the phrase "an unautotomic curve" would certainly sound more pleasantly to the ear than "an anautotomic" one.

ARTHUR S. THORN.

4, Malcolm Road, Penge, S.E., October 25.

THE PRESENT CONDITION OF THE INDIGO INDUSTRY.

OF late years attention has often been drawn to German Technical Chemistry, more especially in connection with the advance and growth of the coal-tar colour industry, an industry which received its birth in this country, but which has now taken up its abode on the continent, the loss of the industry to this country being largely due to the conservatism of our manufacturers, and also partly to the want of proper scientific training on the part of the few chemists whom the manufacturers have *deigned* to employ.[1]

Before 1870 the madder plant was very largely cultivated, in order to obtain from it the important dye-stuff alizarin. But in 1869 a process for obtaining alizarin, by fusing anthraquinone sulphonic acid with caustic soda, was patented simultaneously in this country and in Germany. As a consequence the madder plant is now hardly cultivated at all.[2] Now, thirty years later, another and perhaps even more important natural dye-stuff is in jeopardy owing to the advances of German science. The dye-stuff referred to is indigo, which is cultivated in such large quantities in our Indian Empire. If, then, the natural indigo is to be driven out of the market by the artificial substance, prepared from coal-tar products, it cannot fail to exert a great temporary, if not permanent, influence upon the wealth of India. Perhaps, then, a

[1] In the hand-book for the International Exhibition of 1862 (vol. i. p. 120), the following sentences occur: "It is impossible to overrate the importance of the coal-tar dyes to this country. From having the sources of the raw material in unlimited quantities under our very feet, we are enabled to compete most favourably with continental nations in this respect, and we shall soon become the great colour-exporting country, instead of having, as hitherto, to depend on Holland and other countries for our supply of dye-stuffs."

[2] Madder root contains about 1 per cent. of alizarin, and in 1859–1868 the best qualities of Turkey roots fetched 50*s*. per cwt.; this would make the price of alizarin about 45*s*. per lb. When artificial alizarin was first produced, the dry product fetched about 45*s*. to 50*s*. per lb. A 20 per cent. paste of alizarin is now sold for 7*d*. per lb.

brief survey of the processes employed for producing the natural and artificial indigo may be of interest.

Indigo is one of the oldest dye-stuffs known, having been used in India and Egypt before the Christian era. Egyptian mummies are sometimes found with wrappings which have been dyed with indigo. The ancient Romans and Greeks were also familiar with this dye-stuff. Pliny the Younger mentions indigo in his writings, and in this connection it is interesting to note that adulteration of commercial articles was even practised in his days, for he states that indigo was at times adulterated with the excrement of pigeons and with chalk coloured with woad, but he says the pure article may be known by its burning with a purple flame when heated. Indigo was not introduced into Europe until the sixteenth century, and even then, owing to the strong opposition of the woad cultivators,[1] it was a long time before it came into general use. Indeed, so strong was the opposition and so great was the influence of the woad cultivators, that the employment of indigo was prohibited in England, France and Germany, its use in France being in the time of Henry IV. punished by death, it being called "Devil's Food." However, notwithstanding this powerful opposition, the employment of indigo as a dye gradually gained ground until to-day woad is scarcely cultivated and is no longer employed as a colouring matter, but is used in a certain process of indigo dyeing to cause fermentation and reduce the insoluble indigo blue into soluble indigo white.

The indigo plant (*Indigofera tinctoria*) belongs to the natural order Leguminosæ. It is obtained chiefly from India, especially from the provinces of Bengal, Madras and Oude. But it is also grown in some parts of Africa, in Java, China, Japan, Central America and Brazil. The land is ploughed in October or November, and the seed sown at the end of March or the beginning of April. The growth is very rapid, and the plant attains a height of about three feet. It is cut for the first time between the middle of June and the beginning of July. Two months later a second crop is taken, but the yield is smaller than that of the first crop. The land on which the indigo is cultivated is frequently very poor, and contains very little nitrogen, yet indigo is grown on the same land from year to year with only very occasional change of cropping, and this in spite of the fact that practically the only manure employed is *seet*, *i.e.* the indigo refuse, leaves, stalks, &c., which have been taken from the steeping vats. Notwithstanding, the crops obtained from year to year do not show much deterioration either in yield or quality. Dr. D. A. Voelcker, in his report on Indian agriculture, suggests that since indigo belongs to the order Leguminosæ, and it has been shown that certain legumes are able to absorb atmospheric nitrogen through the medium of *nodules* which form on the rootlets, that perhaps the indigo plant obtains the nitrogen it requires in this manner. The writer of this article is, however, not aware whether the subject has been investigated.

The dye indigo does not occur ready formed in the plant, but exists in the form of a glucoside called indican. This glucoside was isolated by Schunk. It is a brown, transparent, uncrystallisable syrup, which, by the action of dilute acids, is split up into indigotin (the colouring matter of indigo) and a sugar called indiglucin. A reaction similar to this is supposed to take place during the fermentation process in the production of natural indigo.

Manufacture.

The cut plant is tied into bundles, which are then packed into the fermenting vats and covered with clear fresh water. The vats, which are usually made of brick lined with cement, have an area of about 400 square feet and are 3 feet deep, are arranged in two rows, the tops of the bottom or "beating vats" being generally on a level with the bottoms of the fermenting vats. The indigo plant is allowed to steep till the rapid fermentation, which quickly sets in, has almost ceased, the time required being from 10–15 hours. The liquor, which varies from a pale straw colour to a golden-yellow, is then run into the beaters, where it is agitated either by men entering the vats and beating with oars, or by machinery. The colour of the liquid becomes green, then blue, and, finally, the indigo separates out as flakes, and is precipitated to the bottom of the vats. The indigo is allowed to thoroughly settle, when the supernatant liquid is drawn off. The pulpy mass of indigo is then boiled with water for some hours to remove impurities, filtered through thick woollen or coarse canvas bags, then pressed to remove as much of the moisture as possible, after which it is cut into cubes and finally air-dried.

Another method is to treat the plant with dilute ammonia or alkalis. This method is said to more completely decompose the indican, and thus to give a larger yield of indigo.

The value of indigo as a dye-stuff depends upon the quantity of indigotin which it contains. The percentage of indigotin in the natural indigo varies from 20–90 per cent. Beside indigotin, natural indigo also contains small and varying quantities of indigo red, indigo brown and indigo gluten. The following is an analysis of a good sample of Bengal indigo :—

Indigo blue	61·4 per cent.
Indigo red	7·2 ,,
Indigo brown	4·6 ,,
Indigo gluten	1·5 ,,
Mineral matter	19·6 ,,
Water	5·7 ,,

Artificial Indigo.

After many years of careful and laborious *scientific* work, artificial indigo is beginning to compete with natural indigo, and there seems to be but little doubt that, unless the producers of the natural article are able to improve the process of manufacture, in the near future the artificial product will, in all probability, get the upper hand in the struggle. Engler and Emmerling appear to have been the first chemists to obtain artificial indigo. They obtained it by the action of zinc dust and soda lime upon ortho-nitroacetophenon, but the quantity obtained was very minute, and, as the mechanism of the reaction was not at that time understood, it did not much help in paving the way for further research work. For most of our present knowledge of indigo we have to thank von Baeyer, whose work on indigo may be looked upon as one of the chemical triumphs of the century. So far back as 1868, von Baeyer obtained indol directly from indigo, and, in the following year, in conjunction with Emmerling, he prepared this substance by fusing crude nitrocinnamic acid with caustic potash and iron filings ; shortly afterwards they discovered that by the action of phosphorus trichloride, phosphorus and acetylchloride on isatin, a product was obtained, which, when exposed in aqueous solution to the action of the air, gradually deposited indigo ; this method was subsequently improved. In 1875 Nencki obtained indigo by the oxidation of indol with ozone. But it was not till the year 1880 that any great progress was made in the synthesis of indigo. In this year von Baeyer published a series of brilliant researches showing how indigo could be obtained from ortho-nitrocinnamic acid. He showed that when ortho-nitrocinnamic acid is subjected to the action of bromine, ortho-nitrodibromcinnamic acid is obtained, which when treated with alkalis in the cold is converted into ortho-nitrophenylpropiolic acid, and this substance, on being warmed with a dilute solution of caustic soda and grape sugar, or some other alkaline reducing agent, is converted into indigo, the yield compared with

[1] The colouring matter of woad, *Isatis tinctoria*, is indigo.

that theoretically possible being 70 per cent. Von Baeyer also showed that, by acting upon ortho-nitro-cinnamic acid with caustic soda and chlorine, ortho-nitro-phenylchlorolactic acid was produced, which on treatment with alcoholic caustic potash was converted into ortho-nitrophenyloxyacrylic acid, and this on being fused yields small quantities of indigo. Owing, however, to the high cost of ortho-nitrocinnamic acid, indigo so produced could not enter into competition with the natural dye. In 1882 von Baeyer and Drewson brought out yet another synthesis. They found that, by acting upon a mixture of ortho-nitrobenzaldehyde and acetone with caustic soda, indigo was produced, and, further, if the starting products were pure, that the yield of indigo was 80 per cent. of that theoretically obtainable. In 1890 Heumann discovered that when phenyl glycine was melted with caustic soda, taking care that air was, so far as possible, excluded, a yellow-coloured fuse was obtained. This fuse, on being dissolved in water and exposed to the action of the air, produced indigo.

Unfortunately, although the low price of the materials employed should have caused this to be a successful manufacturing process, the yield of the dye-stuff was very poor. Heumann shortly afterwards showed that a very much better yield could be obtained by employing phenylglycine-ortho-carboxylic acid, but although the yield was better the cost of production was higher, the more expensive anthranilic acid taking the place of the cheaper aniline as a starting product. Of late, however, the price of anthranilic acid, owing to improved methods of manufacture, has fallen very considerably, and, doubtless, will continue to fall. Indigo can also be obtained by fusing bromacetanilid with caustic potash, the indol so produced being oxidised by the action of the air to indigo. Again, when ortho-nitroacetophenone is carefully heated with zinc dust, a sublimate of indigo blue is obtained. There are many other syntheses of indigo known, but the majority of them are of more theoretical than practical importance.

Of the many methods for obtaining artificial indigo, only two or three modifications are employed for manufacturing the dye. These are von Baeyer's ortho-nitro-benzaldehyde and aceton synthesis, and that of Heumann from o-phenylglycinecarboxylic acid. But beside indigo itself there is a substance sold under the name of "indigo salt," which is the sodium bisulphite salt of the methylketone of o-nitrophenyl-lactic acid. It is readily soluble and is used for indigo printing.

Artificial indigo as brought into the market contains over 90 per cent. of indigotin, whereas in the natural product the quantity varies from 20 to 90 per cent. The artificial product, however, contains no indigo-red, indigo-brown, or indigo-gluten; whereas these substances are present in natural indigo, and exert an influence in dyeing certain shades of indigo. Indigo itself cannot be employed for dyeing owing to its insolubility. But when subjected to the action of reducing agents it is converted into *indigo-white*, which is soluble in alkalis. Wool or cotton dipped into such a vat and then exposed to the action of the air become dyed a fast blue.

One would have supposed that the indigo producers would have taken warning from the extinction of the artificial alizarin industry, and called to their aid experienced agriculturists to see if it were not possible to increase the yield and quality of the indigo plant, and chemical experts to endeavour to improve the process of manufacture. This, however, has not been done. The planter appears uncertain whether thick or thin seeding is the better, whether any other manure except *seet* should be employed. Again, whether the *seet* should be applied to the land fresh or whether it should first be allowed to ferment. The manufacturing is entirely conducted by "rule of thumb." It is a matter of dispute as to whether the bundles of indigo plant should be packed tightly or loosely in the vats. If the water employed should be hard or soft is purely a matter of individual opinion. Again, it is a question of debate as to how long the cut plant should be steeped, &c. The Badische Anilin Soda Fabrik is said to have invested 500,000*l.* in plant for the manufacture of artificial indigo. Will British (Indian) manufacturers never lay out capital in scientific investigation? Will they *never* realise that money so laid out is almost certain in the near future to bring in a rich return? In conclusion, I give the following quotation from the report on the trade of Frankfurt for 1899, by Consul-General Sir Charles Oppenheimer:—

"In the territories in which natural indigo is grown, the intensity and magnitude of the danger which lies in the advance of the artificial product ought not for a moment to be disregarded. The struggle between artificial and natural indigo has already commenced. The latter still shows some advantages, inasmuch as its bye-products, such as indigo gluten, indigo red, &c., aid the dyeing process to some extent. If natural indigo is to retain its position, every effort must be directed in a rational manner to organising its culture towards the manner in which it is collected, and the way the dye is shipped. In order to obtain a favourable result, the ablest experts should co-operate in this important task. To-day the fate of East Indian indigo culture lies unfortunately in the retorts of the chemical factories."

F. MOLLWO PERKIN.

THE FORM AND SIZE OF BACTERIA.

BACTERIA is a generic term that has been applied to an extensive group of single-celled organisms belonging to the lowest forms of plant life The bacteria obtain their nutriment from organic matter, either dead or living, and are therefore capable of leading a saprophytic or a parasitic existence. They are amongst the smallest forms of life with which the biologist has to deal, the transverse diameter of the individual cells seldom exceeding a few micro-millimetres, or it may be a fraction of a micro-millimetre. The highest powers of the microscope are consequently necessary for the study of their structure, which is of a simple character, consisting essentially of protoplasm with a containing cell-membrane. The most striking differences are to be found rather in the biological properties of the bacteria as promoters of decomposition, putrefaction and fermentation, or as the originators of morbid processes in plants and animals, than in any distinctive features they possess as vegetable cells. The following account is simply intended to give the reader who is not a specialist a general conception of the main types of these organisms, which form the special study of bacteriology.

It may, in the first instance, be pointed out that though the bacteria are microscopically minute organisms, yet considerable variations in shape and size occur. The illustrations in the accompanying plate have been selected to illustrate these two points. It will be seen that, for example, amongst the most widely known pathogenic organisms the variation in form is considerable, whilst in point of size the largest of these is many times greater than the smallest. Bacteriology is at present largely dependent for a classification of the bacteria upon the variations that occur in their shape. The individual cells multiply by a process of fission, and the fundamental forms are spherical, oval, rodlike or spiral in shape. At the same time the species cannot be entirely determined by the microscopic appearance. In fact, there are many organisms which it is impossible to identify until other characteristics, such as the macroscopic appearance of their artificial growth on suitable media, or their pathogenic effects on animals, have been observed. The fact has also to be remembered that a

particular organism may under different conditions assume changes in shape, and that even under apparently the same conditions variations in shape and size may occur.

The organisms of a spherical shape are termed Cocci, the individual cells appearing as spheres, except during the period of fission, when elongated or lance-shaped forms occur—e.g. *Diplococcus pneumoniae.* The mode of cell-division determines the nomenclature applied to the various classes of cocci—those dividing in one direction and remaining attached in pairs or chains are termed diplo- or strepto-cocci; those dividing in two directions and forming groups of four—tetracocci; those dividing in three directions and forming packets—sarcinæ; and those dividing irregularly into grape-like clusters—staphylococci.

The standard of measurement for bacteria is the *mikron*, equal to 1/1000 part of a millimetre, and represented by the sign μ. The diameter of the cocci varies from about $0{\cdot}3$ to 3μ.

The organisms in which the length is always greater than the breadth are termed bacilli. Their shape is cylindrical, and they assume a rod-like form; of the most important forms the length may vary from $0{\cdot}5\mu$ to $3{\cdot}5\mu$, and the breadth from $0{\cdot}5$ to $0{\cdot}8\mu$. The bacilli may occur isolated, in pairs, or in chains.

The third main group, the spirilla, are spiral in shape, or more accurately their form represents the fraction of the thread of a screw. The spirilla, like the bacilli, divide in one direction, and may occur as comma, S-shaped or corkscrew forms. The cholera organism has a diameter of about $0{\cdot}4\mu$.

The transverse diameter is usually taken as the standard of measurement, as it is more constant than the long diameter of the bacteria.

The dimensions of the organisms shown in the accompanying illustrations are as follows:—*Streptococcus pyogenes*, $0{\cdot}6$–$0{\cdot}8\mu$; *Staphylococcus pyogenes aureus*, $0{\cdot}7$–1μ; *Diplococcus pneumoniae*, $0{\cdot}5$–$0{\cdot}8\mu$; *Bacillus pestis*, B. $0{\cdot}6\mu$, L. $0{\cdot}6-1{\cdot}9\mu$; *Spirillum cholerae*, B. $0{\cdot}4$–$0{\cdot}6\mu$, L. $0{\cdot}8$–2μ; *Bacillus typhosus*, B. $0{\cdot}6$–$0{\cdot}8\mu$, L. 1–$3{\cdot}2\mu$; *Bacillus tetani*, B. $0{\cdot}5\mu$, L. $1{\cdot}2$–$3{\cdot}6\mu$.

The example seen in Fig. 1 is the *Streptococcus pyogenes*, which is responsible for various septic processes in man. The grouping into chains is a characteristic feature of this organism. There is little variation in size of the individual members of the chain, with the exception of detached or isolated cells, which may be double the size of the normal cocci, *e.g.* when cell-division occurs. Micrococci are not generally subject to such individual variations as bacilli, as can be seen in Fig. 2, *Staphylococcus pyogenes aureus*, where only slight variations in size are to be detected. In Fig. 3 is an example of a very pleomorphic organism, the plague bacillus. It is ordinarily a very short, thick rod, almost appearing as a diplococcus when subdivision occurs. In the photograph, one rod is seen which is about six times the size of the others, and this is by no means uncommon. In a fluid culture the form of the plague bacillus is entirely altered, the organism almost assuming the appearance of Fig. 1. The *Micrococcus pneumoniae* (Fig. 4) is one of the most variable of the diplococci, the individuals in a pair being rarely equal in size, and sometimes elongated, as seen in the photograph. The cholera organism (Fig. 5) is inconstant in size, and its chief characteristic is the bent rod or comma shape. The tetanus bacillus (Fig. 6) is of large size in relation to the other organisms noticed. It is usually a straight rod, except when spore-formation occurs, when it assumes the drum-stick appearance, as seen in the photograph. The typhoid bacillus (Figs. 7 and 8) is very variable in size, although its rod-like shape is constant. The organisms generally have been stained with gentian violet, except in Fig. 8, where Van Ermengem's method for demonstrating flagella has been adopted. This process is not a true staining method, it is really a deposit of a silver-salt on the organism and its flagella. The organism appears much larger than when stained in the ordinary way. Many organisms are like the typhoid bacillus, endowed with flagella, which are probably exclusively organs of locomotion. In Fig. 8 they surround the bacillus, and are many times longer than the organism itself. In other organisms one finds sometimes unipolar or bi-polar flagella.

The illustrations accompanying this article have been produced in the photographic laboratory of the Jenner Institute of Preventive Medicine. The magnification is in all cases 1750 diameters, this being regarded as the highest at which satisfactory photographs of bacteria can be taken, a higher magnification generally resulting in the outline of the organism becoming blurred. The objectives used were a Zeiss 3 mm. apochromatic and a Winkel $1{\cdot}8$ mm. fluorite system, low-power projection oculars being used in each case, and magnification obtained by suitable camera extension. The organisms were all stained, so that a yellow screen was necessary when photographing. The screen used was a saturated solution of acridine yellow, about 15 mm. thick, and with this uniformly satisfactory results have been obtained.

ALLAN MACFADYEN.
J. E. BARNARD.

NOTES.

THE 101st anniversary of the death of Domenico Cirillo, friend of Linnæus, and famous both as botanist and physician, occurred on Monday, October 29. The account of the life and work of this great Neapolitan, given by Prof. Giglioli in another part of the present issue, appears, therefore, at a very appropriate time, and will be read with much interest by every naturalist. We are glad to be able to publish this appreciative notice of some of Cirillo's contributions to science, and thus to add to the number of those who, knowing his works and career, will cherish his memory.

THE announcement of the death of Prof. Max Müller, at Oxford on Sunday last, has been received with universal regret. The funeral has been arranged to take place to-day at Holywell Cemetery, Oxford.

ACCORDING to a *Times* report from Constantinople, "An Imperial Iradé prohibits star-worship and Sabianism in Turkey." It would be interesting to know more exactly what has been prohibited.

THE new science laboratories at King's College were opened by Lord Lister on Tuesday afternoon.

THE death is announced of Mr. William Anderson, professor of anatomy to the Royal Academy of Arts, and the author of a number of works on surgery and anatomy.

A COURSE of Cantor lectures by Prof. J. A. Fleming, F.R.S., on "Electric Oscillations and Electric Waves," will be delivered on Monday evenings in November and December at the Society of Arts.

A DESTRUCTIVE series of earthquake shocks occurred at Caracas, the capital of Venezuela, and the surrounding districts on Tuesday, October 30. The town of Guaronas has been entirely destroyed.

A VISIT to the Chelsea Physic Garden is enough to convince any one of the urgent need of new greenhouses to replace the dilapidated structures in which the existing collections are housed. A more ruinous building than the central range it would be

difficult to imagine, and unless new accommodation be speedily provided for its inmates, the winter's mortality amongst them must be very great. We understand that plans for the erection of new planthouses have for some time been under consideration, and it is much to be hoped that they may be followed by tangible results with as little delay as possible. Under the new *régime*, the garden, with its increased resources, is proving of great use to institutions in which botany forms part of the curriculum, and it would be a great pity if, owing to avoidable damage, its growing utility should be impaired.

IT is stated in the *Bulletin* of the American Mathematical Society that the Steiner prizes of six thousand marks, which were not awarded, owing to no papers being presented, have been divided into three parts which have been given to Prof. Karl Friedrich Geiser, Zurich, for his researches in geometry and his services in the publication of Steiner's lectures; to Prof. David Hilbert, Göttingen, for his researches on the axioms of geometry and for the advancement which analytic geometry has experienced from his work on the theory of of invariants, and to Prof. Ferdinand Lindemann, Munich, who has earned special distinction in geometry by his celebrated discussion of the quadrature of the circle, as well as by editing Clebsch's "Vorlesungen über Geometrie."

THE Senate of New York University has (says *Science*) received and confirmed the votes of its judges selecting thirty eminent native-born Americans whose names are to be inscribed in the "Hall of Fame," now in course of construction on University Heights, New York City. The Americans selected as the most eminent are distributed as follows: Rulers and statesmen, 7; authors, 4; inventors, 4; preachers and theologians, 3; judges and lawyers, 3; soldiers and sailors, 3; men of science, 2; philanthropists, 2; educators, 1; painters, 1. The inventors on this list are Fulton, Morse, Whitney and Howe, and the men of science Audubon and Gray. Franklin is of course also included. Of the hundred judges appointed, ninety-seven voted and the votes cast for men of science were as follows: John James Audubon, 67; Asa Gray, 51; Joseph Henry, 44; Matthew Fontaine Maury, 20; Benjamin Thompson, 19; Benjamin Silliman, 16; Benjamin Peirce, 14; Nathaniel Bowditch, 10; Alexander B. Bache, 9; Spencer Baird, 8; Henry Draper, 8; Maria Mitchell, 7; David Rittenhouse, 6. Twenty further names are to be selected in 1902 by the same judges.

REFERENCE has already been made to the medal which the Queensland Branch of the Royal Geographical Society of Australasia has decided to award. From a circular that has reached us, we learn that the medal has been instituted in recognition of Mr. J. P. Thomson's services to the Society, and is to be called "The Thomson Foundation Medal." It will be awarded annually, or at such other times as the Council may approve, to the author of the best original contribution to geographical literature.

IN memory of the late Dr. R. T. Manson, F.G.S., a well-known naturalist and geologist, a large granite boulder has been taken from the bed of the River Tees and placed on a pedestal in the Public Park, Darlington. The stone weighs about twelve tons, and it is admitted to have come originally from Shap, in Westmorland, in the Great Ice Age. It had been deposited 300 yards above Winston Bridge on the shape and limestone bed of the Tees, where the formation is of the carboniferous age.

THE Board of Education have received, through the Foreign Office, copies of the official translation of the statutes and regulations of the Nobel Bequest. It will be remembered that Dr. Nobel left a large sum, the interest on which was to be devoted to prizes to those who in the course of the previous year should have rendered the greatest service to mankind. The amount thus available was to be divided into five equal parts, to be assigned as follows:—(1) To the most important discovery or invention in the domain of the physical sciences; (2) To the most important discovery or improvement in chemistry; (3) To the most important discovery in physiology or medicine; (4) To the most remarkable literary work (l'ouvrage littéraire le plus remarquable dans le sens de l'idéalisme); and (5) To the person who should have rendered the greatest service in the cause of international brotherhood, in the suppression or reduction of standing armies or in the establishment or furtherance of Peace Congresses. The competition was open to the whole world. It has been found necessary to embody the testator's wishes in a somewhat lengthy and complicated body of statutes. The Board of Education are causing copies of the official translation in French) of these statutes to be transmitted to a number of the chief libraries in England and Wales, to the Universities and University Colleges, to a number of learned societies and to the Press. The regulations for the competition (which will, if possible, be held for the first time in 1901) can thus be consulted by persons interested in the matter.

IT is proposed to publish in separate volumes the lectures on the principles of geology, delivered at the Johns Hopkins University, under the George Huntington Memorial Fund; and subscriptions for the volumes are invited by Prof. W. Bullock Clark, Baltimore, Maryland, U.S.A. The lectures have been given by geologists of international reputation, a fund having been provided for that purpose by the generosity of Mrs. Williams, who thus commemorates the name and work of her husband, formerly professor of inorganic geology in the Johns Hopkins University. The lectureship was inaugurated in April, 1897, by Sir Archibald Geikie, who delivered six lectures on "The Founders of Geology," which have already been published by Messrs. Macmillan and Co. A second course was given in April, 1900, by Prof. W. C. Brögger, who delivered two lectures on the principles of a genetic classification of the igneous rocks, followed by five lectures on the late geological history of Scandinavia, as shown by changes of level and climate since the close of the glacial epoch. Other lectures will be delivered from time to time and will be published in a uniform style. The volumes will thus contain authoritative opinions regarding the fundamental facts of geological science.

THE first place in the *Quarterly Review* is given to a descriptive account of malaria and its relation to mosquitoes, in which some of the facts in seven recent volumes and reports dealing with the subject are considered. To any one who has not had before him the statistics as to the number of deaths from malaria, the mortality from the disease is astonishing. It has been said that one half the mortality of the human race is due to malaria, and though this may very well be an exaggeration, the figures given in the review show the deadly character of the disease and the vast extent of its field of activity. Apart from the mortality, it is stated that the disease probably levies a heavier tribute in the capacity of the officers and officials who administer the British Empire than does any other single agency. Laveran's discovery, in 1880, of the small organism responsible for the disease is, therefore, worthy of greater glory than the victories of any general or the triumph of any political party, for it has greater influence upon human affairs. Lankester had previously described a parasitic organism living in the blood-cells of a frog, and these purely scientific observations laid the foundation for the mosquito-malaric theory propounded by Dr. Manson, and established by the brilliant researches of Ross, Grassi, Bastianelli, Bignami and others. The whole story is told in the review, and it affords another instance of the far-reaching value of scientific work which at the commencement appears to have no practical applications.

In the Geological Series, Vol. i., No. 7, of the Field Columbian Museum publications, Dr. O. C. Farrington describes some new mineral occurrences in America. These include, amongst others, the rare inesite from a mine near Villa Corona, Mexico, a mineral which is only known from three other localities in the world; also some curious crystals of golden calcite from the Bad Lands region, which exhibit such distortion as to have an apparent prismatic form. There is an interesting note also on the use of dolomite as money by the Pomo Indians, inhabiting Lake County, California. The dolomite money is fashioned by cutting symmetrically-shaped cylindrical pieces from the rough pebbles. These are afterwards burned to bring out streaks of a reddish colour and are then polished and perforated. It is stated that a well-worked piece is estimated at almost the value of its weight in gold. A second section of this publication deals with some interesting crystal forms of calcite from Joplin, Missouri, which are remarkable "not only for their size, but for their transparency, varied colour and the perfection of their crystal form." The paper is well illustrated.

IN an article on "The Orange River Ground Moraine" (*Trans.* S. African Phil. Soc. vol. xi. part 2, September 1900), Messrs. A. W. Rogers and E. H. L. Schwarz describe the glacial characters of the Prieska conglomerate which occurs beneath the Kimberley shales. In their opinion it is a true till formed by land-ice; numerous striæ are to be found on the boulders, while the rock-surfaces underlying the conglomerate are clearly glaciated. A number of photographic plates support the conclusions of the authors. They remark that the relationship between the Prieska conglomerate and that known as the Dwyka conglomerate is still uncertain. The Dwyka conglomerate forms the base of the Mesozoic group, and has long been regarded as of glacial origin. An important paper on the chemical composition of the soils of the south-western districts of Cape Colony is contributed to the same publication by Mr. Charles F. Juritz.

PROF. W. M. DAVIS announces (*Appalachia*, vol. ix., March 1900) that his doubts as to the ability of ice to erode deep valleys and basins have been dispelled by a study of the valley of the Ticino, towards St. Gotthard. The fact that the side valleys open into the main valley several hundred feet up, indicates that the ice-stream, while deepening the main channel, rose high enough to prevent the small lateral glaciers from exercising much erosive power on their courses. In a second article (*Proc.* Boston Soc. Nat. Hist., vol. xxix., July 1900) Prof. Davis pursues the subject of "Over-deepened main valleys and hanging lateral valleys," and deals also with the excavation of lake-basins by ice-action.

THE well-known formula for the velocity of propagation of capillary waves or "ripples" shows that the surface-tension of a liquid can be determined experimentally by observing the wave-length and velocity, or the wave-length and frequency of such waves. Dr. Leo Grunmach, of Berlin, has successfully applied this method to liquids, and he now communicates to the *Sitzungsberichte* of the Berlin Academy an account of determinations of the capillary constants of liquefied gases by the same method. The waves are excited by a tuning-fork with needle points dipping into the liquid, and the interference-curves enable the wave-lengths to be measured with considerable accuracy. The method has been applied to liquefied sulphurous acid, Pictet's fluid (a mixture of 64 parts by weight of sulphurous acid with 44 parts carbonic acid), liquefied ammonia and liquefied chlorine, and the values of the capillary constants will, it is surmised, lead to interesting results in connection with critical point investigations.

THE smallest lateral difference of place that is just visible has, until recently, been given as about 50″ to 1′ angular measure. The method employed by Helmholtz and others in reaching this result was the well-known one of bringing two parallel lines together until they finally are just distinguished as two. Prof. George M. Stratton, writing in the *Psychological Review* for September, describes a different method by which it is now evident that a lateral difference of place of about 7″ of arc can be directly perceived. Instead of using lines or points side by side, the experiments which gave this result were made with lines end to end, so arranged that the upper of two perpendiculars could be moved at will to the right or left, while still remaining exactly parallel to the lower line. The observer had simply to judge whether the upper line was continuous with the lower or to which side it was displaced. The results, which gave 7″ as the threshold of space distinction under these conditions, are interesting, as explaining Bourdon's experiments, according to which a difference of position amounting to but 5″ gives a perceptible stereoscopic effect.

MR. FRANK B. WILLIAMS contributes to the *Proceedings* of the American Academy of Arts and Sciences a paper on the geometry on ruled quartic surfaces. Of the quartic scrolls Cremona enumerates twelve, while Cayley divides these scrolls into ten species, stating that Cremona's two remaining species, though properly considered as distinct from the others, may be regarded as sub-forms of his seventh and ninth species. These two are the developable quartic or torse, whose edge of regression is a twisted cubic, and the quartic cones. It is the purpose of Mr. Williams's paper to consider the classification of curves on all ruled quartic surfaces, to find the formula for the number of intersections of any two curves that lie on the same ruled quartic surface, and to point out some of the most notable results obtained in the course of the investigation. The equations of many of the ruled quartic surfaces are so complicated that very serious difficulties arise when we attempt to treat them analytically, and the author finds it convenient to employ the synthetic method of Prof. Story.

MR. F. J. ROGERS, in the August number of the *Physical Review*, advocates the use of the M.K.S., or metre-kilogram-second, system of units in solving problems in mechanics where solutions involving the C.G.S. units of force and work lead to enormously large numerical measures. The author remarks that the common mode of abbreviating these large numbers by using powers of ten gives some trouble to beginners. Mr. Rogers suggests that the corresponding absolute unit of force may be called the large dyne, or the *Dyne* spelt with a big D; but this nomenclature seems capable of improvement in order to avoid confusion with the megadyne, which contains ten of his large dynes.

A SERIES of interesting experiments on the explosive effects of the modern infantry bullet have been carried out in Germany by C. Cranz and K. R. Koch. They used a new Mauser rifle of 6 mm. bore, having a muzzle velocity 100 m. greater than "Model 88." To imitate the effect upon large blood-vessels, while at the same time obtaining simple physical conditions, the experimenters constructed short hollow tin cylinders filled with water, and closed at one end with a sheet of rubber, and at the other with a sheet of parchment paper. Electrodes were mounted before or behind the cylinders, or inside them, and the discharge spark produced by the bullet was utilised to obtain a photograph of its silhouette at various points of its path. Among the important facts thus elicited it appears that the body struck is not displaced by the entry of the bullet. On leaving the body, the bullet carries away with it a small part of the hind surface, having a small round perforation through which the bullet passed. The "explosion" does not take place until the bullet has left the body. After discussing the evaporation, hydraulic-pressure, rotation, and sound-wave theories of the explosion, and discarding them all, the authors conclude that

the apparent explosion is due to the transfer of kinetic energy to the portions hit at later stages, which are thus torn away from those first encountered.

WE have received from Dr. W. Doberck a copy of the observations made at the Hong Kong Observatory during the year 1899, containing hourly values and results of the principal meteorological elements. The volume is the sixteenth of this important series, and the observations are enhanced in value by the fact of their publication on a uniform plan, which admits of comparison of the means of one year with those of another. The weather forecasts show a high degree of success; following the method of analysis usually adopted, and adding together the sum of total and partial success, the percentage amounts to 94. The collection of observations made in the eastern seas and their collation in one-degree squares, for the construction of trustworthy pilot charts, are actively carried on, and these observations are supplemented by registers kept at forty stations on shore. Astronomical and magnetic observations are also regularly made, and the results published in the volume above referred to. The time-ball was successfully dropped throughout the year, with only seven cases of failure.

IT was only in 1889 that Dr. Merriam, in the "North American Fauna," published a synopsis of the pocket-gophers of the genus Perognathus; but since that date a host of new species and races have been described. Accordingly, a revision of the group has been found necessary, which has been carried out by Mr. W. H. Osgood in No. 18 of the publication cited, several new forms being added to the already large list.

WE have received parts iii. and vi. of "Papers from the Harriman Alaska Expedition" (*Proc. Washington Academy*, vol. ii.), the former, by Mr. W. E. Ritter and Miss G. R. Crocker, dealing with the multiplication of rays in a 20-rayed starfish and its bilateral symmetry, and the latter, by Miss A. Robertson, treating of the Bryozoa. The most interesting feature in connection with the starfish (*Pycnopodia helianthoides*) is the presumed relation between one of its arms and the so-called larval organ of the embryo. In regard to the Bryozoa, Miss Robertson remarks that many of the Alaskan species are common to Queen Charlotte Islands, Paget Sound and California. The distribution of all the forms found on the western coast of North America is given, several new species being described.

THE first half of Part iv. of vol. xxviii. of the *Morphologisches Jahrbuch* is taken up by the final instalment of Dr. S. Paulli's important memoir on the pneumatic cavities in the mammalian skull. It is concluded that the homology of these cavities can only be determined by means of their relations to the nasal chamber, and that the terms "frontal" and "sphenoidal sinus" have no morphological value. In Monotremes, pneumatic chambers are wanting, and in other groups the capacity of these increases with the bodily size of the species in which they occur. The second half of the same fasciculus contains the commencement of a memoir by Prof. L. Bolk on the anatomy of apes, the gravid uterus of the langur (Semnopithecus) being the first subject for consideration.

DR. A. B. MEYER, the Director of the Dresden Museum, has sent us the first instalment of a work entitled "Ueber Museen des Ostens der Vereinigten Staaten von Nord Amerika; Reisestudien." In the autumn of 1899, Dr. Meyer undertook a journey to the States for the purpose of inspecting the museums and their methods of arrangement and conservancy, and the present issue describes some of the results of his survey. As is well known, Dr. Meyer has paid particular attention to the construction of museum cases and cabinets, and he seems to have been much interested in some of those in use in America. The present part, which is lavishly illustrated, deals with the museums of New York City, Albany and Buffalo. One of the most striking photographs represents the gallery of Mexican antiquities in the American Museum of Natural History, New York.

WE have received "Verhandlungen der Deutschen Zoologischen Gesellschaft auf der zehnten Jahresversammlung zu Graz, den 18, bis 20, April 1900," which contain a number of short papers on zoological subjects chiefly interesting to specialists. We have likewise been favoured with copies of the *Bulletin International de l'Académie des Sciences de Cracovie*, *Comptes rendus*, for May and July 1900. Among other papers, the latter contains a communication, by M. E. Godlewski, on the effects of oxygen on the development of the embryo of the frog; and a second, by M. S. Maziarski, on the structure of the salivary glands. The last-named author has succeeded in modelling these glands on an enlarged scale in wax, and his paper is illustrated by a plate showing some of these models.

THE following lectures will be given at the Royal Victoria Hall, Waterloo Road, during November:—November 6, "Plants of Long Ago," Mr. A. Seward, F.R.S.; November 13, "Flowers from an Insect's Point of View," Prof. J. B. Farmer; November 20, "The Medicinal Wells of Old London," Mr. W. H. Shrubsole; November 27, "Some Unknown Countries north of Tanganyika," Mr. J. E. S. Moore.

THE sixth volume of *The Reliquary and Illustrated Archæologist*, comprising the four quarterly numbers issued this year, has been published by Messrs. Bemrose and Sons. The separate numbers of the magazine have been noticed in these columns as they appeared, but this need not prevent us from remarking that Mr. Romilly Allen, who edits the publication, and his fellow archæologists, are to be congratulated upon the excellent character of the text and illustrations of their organ.

DR. M. C. COOKE's book entitled "One Thousand Objects for the Microscope" is well known to microscopists, and the new edition, which has just been published by Messrs. Frederick Warne and Co., is likely to have an even wider sphere of usefulness. Originally, the book consisted of a list of objects, with brief notes upon their microscopic characteristics. Preceding this, Dr. Cooke now gives a description of the microscope and its essential accessories, with hints on their manipulation, and on the collection and mounting of the different classes of objects enumerated. The book is thus now a complete guide for beginners of practical microscopy, and will be of assistance to all who have a microscope and wish to know how to make good use of it.

THE number of cases of the production of true nitro-derivatives in the fatty series by direct nitration with fuming nitric acid is practically limited to the work of Franchimont and Klobbie and Ruhemann and Orton on malonic acid derivatives. In the current number of the *Comptes rendus*, MM. Bouveault and Wahl give the results of some successful experiments upon the direct nitration of unsaturated fatty compounds. With the ethyl ester of dimethylacrylic acid, a good yield of a mono-nitro-derivative is formed, which possesses acid properties, forming a potassium salt; from which, on treating with acid, an ethyl nitrodimethylacrylate isomeric with the original compound is obtained.

NEARLY forty years ago Schönbein showed how, on shaking lead amalgam with air and water, equivalent quantities of lead oxide and hydrogen peroxide were formed. In recent years many isolated cases have been described of this so-called autoxidation or simultaneous oxidation of two substances by air, one being incapable of oxidation by air alone—the researches of Bamberger,

and of Manchot in particular, proving the production of hydrogen peroxide in such cases. Engler has recently suggested that probably in all such cases hydrogen peroxide is formed simultaneously, half the oxygen molecule going to oxidise the substance present, and the other atom forming hydrogen peroxide. In many cases the formation of the latter substance is difficult to prove on account of its secondary oxidising action upon the substance used. In the current number of the *Berichte*, Dr. H. Biltz describes experiments on the oxidation of the hydrazone of dibromoxybenzaldehyde in alkaline solution by air at the ordinary temperature, and in this case he has been able to prove that the amount of oxygen in the hydrogen peroxide formed is exactly equal to the oxygen used up by the hydrazone.

THE same number of the *Berichte* also contains an account by Prof. Curtius of what appears to be a new general method of preparing aromatic aldehydes from the corresponding acids. By the action of dilute alkalis upon benzhydrazide,

$$C_6H_5.CO.NH.NH_2,$$

benzalbenzoylhydrazine,

$$C_6H_5.CO.NH.N:CH.C_6H_5,$$

is obtained, and this gives benzaldehyde upon hydrolysis with dilute acids. Prof. Curtius makes no attempt to explain the mechanism of this reaction, but states that a similar reduction in alkaline solution has been found to take place with many acid hydrazides with formation of the corresponding tertiary hydrazones

$$R.CO.NH.N:CH.R,$$

the latter being insoluble substances capable of easy isolation in a pure state, and in good yields. Distillation with dilute sulphuric acid then gives the corresponding aldehyde.

THE additions to the Zoological Society's Gardens during the past week include two Common Marmosets (*Hapale jacchus*) from South-east Brazil, presented by Lady Mackenzie; a Persian Gazelle (*Gazella subgutterosa*) from Central Asia, presented by Mr. B. T. Ffinch; a Red-necked Bustard (*Eupodotis ruficollis* ?) from South Africa, presented by Mr. J. E. Matcham; a Raven (*Corvus corax*), European, presented by Mr. F. Sykes; seven Gold Pheasants (*Thaumalea picta*) from China, presented by Mr. Henry G. Hobbs; a Carrion Crow (*Corvus corone*) captured at sea, presented by Mr. S. T. Henderson; a Bearded Tit (*Panurus biarmicus*), European, presented by Mr. A. R. Gillman; a Spotted Slow Skink (*Acontias meleagris*) from South Africa, presented by Mr. W. L. Sclater; a Green Lizard (*Lacerta viridis*), European, presented by Dr. Dyer; two Severe Macaws (*Ara severa*) from South America, two Spotted Eagle Owls (*Bubo maculosa*) from Africa, a Westerman's Eclectus (*Eclectus westermani*) from Moluccas, six —— Finches (*Munia*, sp. inc.) from India, two Simony's Lizards (*Lacerta simonyi*) from the Canaries, a Mocassin Snake (*Tropidonotus fasciatus*), a Caroline Anolis (*Anolis carolinensis*) from North America, two Leopardine Snakes (*Coluber leopardinus*), two Vivacious Snakes (*Tarbophis fallax*), an Œsculapian Snake (*Coluber longissimus*), a Four-lined Snake (*Coluber quatuorlineatus*), a Lacertine Snake (*Coelopeltis monspessulana*), South European, deposited; two Hog Deer (*Cervus porcinus*), two Dwarf Turtle Doves (*Turtur humilis*), bred in the Gardens.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN NOVEMBER.

Nov. 1. 9h. 11m. Minimum of Algol (β-Persei).
4. 6h. 0h. ,, ,, ,,
6. 9h. 54m. to 10h. 58m. π Arietis (mag. 5·6) occulted by the moon.
6. 13h. 47m. to 14h. 31m. ρ^3 Arietis (mag. 5·5) occulted by the moon.
11. 14h. 38m. to 15h. 56m. 1 Cancri (mag. 5·9) occulted by the moon.
12. 11h. 54m. to 12h. 58m. A^1 Cancri (mag. 5·6) occulted by the moon.
12. 14h. 45m. to 14h. 56m. A^2 Cancri (mag. 5·8) occulted by the moon.
14. 5h. Mars in conjunction with moon. Mars 7° 39′ N.
14–15. Epoch of the November meteors. Leonids. (Radiant 150 + 23.)
15. Venus. Illuminated portion of disc = 0·751.
Mars. ,, ,, ,, = 0·896.
15. Saturn. Outer minor axis of outer ring = 15″·99.
18. 13h. Venus in conjunction with moon. Venus 5° 51′ N.
21. 10h. 53m. Minimum of Algol (β Persei).
21. 19h. 23m. Eclipse of the sun invisible at Greenwich.
23. 5h. Jupiter in conjunction with moon. Jupiter 1° 3′ S.
23–24. Epoch of the meteoric shower of Biela's comet. (Radiant 25 + 43.)
24. 7h. 42m. Minimum of Algol (β Persei).
24. 12h. Saturn in conjunction with moon. Saturn 2° 8′ S.
27. 4h. 31m. Minimum of Algol (β Persei).
30. 6h. 11m. to 7h. 7m. κ Piscium (mag. 5·0) occulted by moon.

FIREBALLS.—On Sunday evening, October 21, there appear to have been a remarkable prevalence of brilliant meteors. They were noticed at about 8h. 35m., 8h. 40m., 9h. 30m., 10h. and 11h. 58m. The first of these was a magnificent object, and it lit up the sky with three flashes which many people mistook for ordinary lightning. The night was very cold and clear throughout the country, and a great number of descriptions of the fireball alluded to have been published in the newspapers. Its flight was exceedingly slow from S.W. to N.E., and it appears to have been directed from a radiant point either in Capricornus or Aquila. The accounts are, however, somewhat conflicting. Near its disappearance the meteor had a height of between 20 and 30 miles over the Midlands, and a detonation was noticed at several places, including Tewkesbury and Clun, Shropshire.

On October 27, 11h. 42m., a magnificent meteor was seen by Mr. Denning at Bristol, traversing a path from 79° + 33° to 56° + 24¾°, and directed from a radiant at 136° + 34°. The object left a brilliant, irregular streak, one section of which remained visible in an opera glass for 13 minutes, during which time it drifted 17° in a southerly direction.

TEMPERATURE OBSERVATIONS DURING SOLAR ECLIPSE.—Mr. C. Martin made a systematic series of temperature observations during the eclipse of the sun on May 28, 1900, and his results are published in the *Scientific Proceedings of the Royal Dublin Society*, vol. ix. pt. 3, pp. 362–364. The observations were made with two instruments, one having a black bulb, the other with a white one. These were mounted about an inch apart on a black wooden post, some six feet high, the bulbs being six inches from any part of the woodwork, and pointed directly towards the sun. Parts of the first stages of the eclipse were rendered inactive by clouds, but for a period of two hours good readings were obtained. These are plotted as curves, the results from the two instruments being given both individually and in combination, the agreement being very close; if anything, the white bulb thermometer moved less quickly than the black,

and is thus the less sensitive of the two instruments. An examination in detail of these curves shows that the temperature was at its lowest about eight minutes after the middle of the eclipse, and began to rise rapidly as the eclipsed portions of the sun became less. The highest reading with the black bulb thermometer before the eclipse began was 63°·7, the lowest during eclipse being 35°·7, showing a fall of 28°. With the white bulb the corresponding readings were 15°·6 and 3° respectively, showing a drop of 12°·6.

DOMENICO CIRILLO AND THE CHEMICAL ACTION OF LIGHT IN CONNECTION WITH VEGETABLE IRRITABILITY.

ONE hundred and one years ago, on October 29, 1799, Domenico Cirillo, the Neapolitan Linnæus, was hanged on the market-place of Naples, together with some of the noblest among Italian men of letters and science. It is especially fitting to remember Cirillo in England, the country which he visited and where he had many friends, and for the literature and science of which he showed a special predilection—a country which unfortunately had such a fatal influence upon his destiny.

The Cirillos of Grumo, a village of Terra di Lavoro, were a family of doctors, naturalists and artists. At the beginning of the eighteenth century Nicola Cirillo was famed, both as a physician and a botanist. Following the best traditions of Neapolitan science, the traditions of Pinelli, of Imperato, and of Maranta, Nicola Cirillo instituted a private botanical garden, the only one then existing in Naples. In 1718 he became a Fellow of the Royal Society of London, and in connection with this Society, then presided over by Sir Isaac Newton, Nicola Cirillo began to collect meteorological data on the climate of Naples. After his death, in 1734, his botanical garden and his collections, together with the famous herbarium of Ferrante Imperato, were preserved, and the garden improved with the more recent systems of classification by Sante Cirillo, painter and naturalist, whose house became a centre of the learning and culture of Naples.[1]

Domenico Cirillo was born in 1739, and so profited by the education and influence of Sante, his uncle, of Nicola Capasso, Francesco Serao, and of other teachers, that at the age of twenty-one, in 1760, he successfully competed for the chair of botany in the University of Naples. Domenico Cirillo, indeed, followed in the track of Nicola, and soon became known both as a botanist and as a physician. In numerous botanical excursions he visited the greater part of the provinces of Southern Italy and Sicily; and he was the first to organise in this country a regular botanical survey, sending out pupils and assistants to collect in different provinces. Thus not only many rare plants were described in his "Fascicoli Plantarum rariorum Regni Napolitani," begun in 1788, but several new species were discovered. At present, in the Italian flora, about thirteen species of phanerogams are retained as first discovered and described by Cirillo.

That period, when men worked under the spell of Linnæus, was a time of great botanical fervour, of *furore botanico* to use Cirillo's expression, in the collecting and investigating of plants. Of Cirillo's early connection with Linnæus, botanists are still reminded by the name of the *Cyrillae*, which the great Swede dedicated to his young Neapolitan correspondent. Indeed, the devotion of Cirillo for Linnæus was so great that, following the impulse of his enthusiastic nature, he raised a monument to him in the old botanical garden of the Cirillo family.

Induced by Lady Walpole, Cirillo visited France and England, becoming connected with D'Alembert, Diderot, Nollet, Buffon, Franklin, Sir John Pringle, and especially with William and John Hunter. He was elected a Fellow of the Royal Society. In 1771 he published in the *Philosophical Transactions* an account of the Manna Tree of Calabria, Sicily and Monte Gargano, describing the method of extracting the manna. The *Philosophical Transactions* also contain his observations, made near Taranto, on the effect of the tarantola bite; Cirillo confirms what Serao, in 1742, had already written on *Tarantism*, dispelling the absurd superstition of the music-cure supposed to be effected by dancing the Tarantella. He observes how in Sicily the tarantola is never dangerous, and the music-cure is unknown.[1]

In the latter part of the eighteenth century, while the Neapolitan kingdom was freeing itself more and more from the baneful Spanish influence, during the early years of the reign of Ferdinand IV. and Maria Carolina of Austria, a spirit of reform and progress had risen in South Italy, and a new impulse was given to research in natural sciences. In medicine, after Francesco Serao and Domenico Cotugno, Cirillo rose above the rest. The researches and teaching of Giovanni Maria Della Torre and of Cirillo opened a new field to the Neapolitan naturalists in microscopical investigations. And around Cirillo, again, a new school of botanists and zoologists and of chemical investigators arose, among whom we may record the names of Filippo Cavolini, Vincenzo Briganti, Gaetano Nicodemi, Antonio Barba, Saverio Macrî, Antonio Fasano, Nicola Pacifico, Vincenzo Petagna, Matteo Tondi, Nicola Andria, Vincenzo Comi. The discoveries of Alberto Fortis in 1783, near Molfetta, where he observed the richness of the soil in nitrates, led to investigations in Naples on the origin of nitre, in which Fortis himself, Melchiorre Delfico, Giuseppe Giovene, Giuseppe Vairo and Zimmermann were chiefly engaged. In geological and mineralogical research Giov. M. Della Torre took the lead, and with him, or shortly after him, worked Ascanio Filomarino duca della Torre, Domenico Salsano, Gius. Gioeni, Gaetano De Bottis, Luigi De Curtis, Vincenzo Santoli, Domenico Tata, Scipione Breislak, Camillo Pellegrini. In 1788 Lazzaro Spallanzani began his tour to the volcanic regions of Southern Italy and Sicily. In those days Sir William Hamilton, during the many years of his residence in Naples, collected information on the Phlegrean Fields, while Ascanio Filomarino was forming his Vesuvian Museum, destined to so short an existence; for the museum and all the other scientific collections in the Filomarino Palace were destroyed in January 1799, when the unfortunate duke and his brother, Clemente Filomarino, the poet (the translator of Young's poems), were burnt as Jacobins by the infuriated Royalist mob.[2]

During this same period some of the more important foreign works were translated into Italian and published in Naples; such as the works of Stephen Hales, of Priestley, Linnæus, and the Agricultural Encyclopædia of Rozier.[3]

Omitting here all mention of his medical and other publications, Cirillo's chief works on botany and entomology were the following:—"Tabulæ botanicæ elementares," 1773; "De essentialibus nonullarum plantarum characteribus," 1784; "Entomologia Neap. Specimen primum," 1787-1790; "De Cypero Papyro," 1787, re-edited at Parma in 1796; "Fundamenta botanica, sive philosophiæ botanicæ explicatio," 1787; "Plantarum rariorum Regni Neapolitani," fasc. i. 1788, fasc. ii. 1793; "Discorsi Accademici," 1789, re-edited in 1799.

In the field of vegetable physiology, the discoveries of Cirillo on the irritability of plants are noteworthy. In that field, together with his contemporary, G. B. Dal Covolo, Cirillo is the

[1] Ferrante Imperato, whose herbarium was preserved in the Cirillo collections, lived at the end of the sixteenth century. In writing his "Historia naturale," printed in Naples in 1599, Imperato put together a museum which soon became known in Europe; for besides having for fellow-workers in Naples B. Maranta and Fabio Colonna, Imperato corresponded with P. A. Mattioli, Gaspard Bauhin, Ulisse Aldovrandi, Melchiorre Guilandino, and others of the foremost botanists of the time. His herbarium is said to have been composed of eighty volumes. The museum of Imperato got dispersed during the plague of 1656, and Nicola Cirillo eventually obtained possession of only nine volumes. After the sacking of Domenico Cirillo's house in 1799, one volume only of the Imperato herbarium was saved, and is now in the Biblioteca Nazionale of Naples. It contains 440 dried plants, *i.e.* about one-seventh of all the plants identified in the days of Imperato and Bauhin. This herbarium, together with the herbarium of Cesalpino, is among the rarest of botanical relics.

Of the herbarium of Domenico Cirillo a small remaining portion is now preserved in the botanical museum of the Agricultural College of Portici, in the care of Prof. O. Comes.

[1] The music-cure for the tarantola bite is still practised by peasants, especially women, in some parts of the province of Lecce and in Calabria. In Cirillo's days the belief in the dangerous and strange effects of the bite of the tarantola was held even by persons high in authority. See Andrea Pigonati, "Sul Tarantismo," Opuscoli Scelti ii. (Milano, 1779). Compare Franc. Serao, "Della Tarantola o sia Falangio di Puglia" (Napoli, 1742).

[2] Duca della Torre, "Descrizione del Gabinetto Vesuviano da lui posseduto" (Napoli, 1796, 2da ed.).

[3] The works of Hales were translated by a lady, Maria Ardinghelli; St. Hales, "Statica dei Vegetabili ed Analisi dell' Aria, trad. dall' Inglese con varie annotazioni da M. A. Ardinghelli" (Napoli, 1756).

St. Hales, "Emastatica, ossia Statica degli Animali. Esperienze idrauliche fatte sugli animali viventi" (Napoli, 1776).

Gius. Priestley, "Sperienze ed Osservazioni sopra diverse Specie di aria, trad. dall' Inglese" (Napoli, 1784).

The translation of Rozier's Encyclopædia was begun in 1783, and was due to the Società Letteraria di Napoli, of which Cirillo was one of the leading members.

Vincenzo Petagna began editing the "Species Plantarum" of Linnæus.

direct successor of his celebrated compatriot, Alfonso Borelli, who, in 1653, discovered in Naples the irritability of the anthers of *Centaurea*, and of other Cynareæ. In his essay, "Del Moto e della Irritabilità dei Vegetabili," published in 1789, Cirillo briefly describes what was then known of the sleep of plants, of the movements of the leaf blade of *Dionoea muscipula*, and of the fly-trap concealed in the flowers of *Aposynum androsaemifolium*, a plant then lately studied by Francesco Bartolozzi in Milan.[1] Cirillo quotes Linnæus' description of the movements of the *Hedysarum gyrans*, first discovered by Pohl in 1779. After describing the irritability of the stamens of the Cynareæ, the gradual sensitiveness of the flowers of Verbascum to shocks, and the recent observations of Duhamel and of others on the stamens of *Berberis*, and of *Parietaris officinale*, Cirillo goes on to describe his own discoveries of irritability in *Forsckohlea tenacissima*, and in the common nettle, *Urtica dioica*. "The study of the very complex fructification of the first plant (*Forsckohlea*) having revealed to me the spiral structure of the filaments, similar to those of *Parietaria*, I was led to verify whether these filaments also possessed irritability. It is of great interest to observe in the nettle, during the warmer morning hours, how the male flowers open abruptly, and suddenly burst open their well-closed anthers, that eject abundant fertilising dust."[2]

These observations brought Cirillo to believe that the "marvellous irritability of the sensitive plant, as well as the elasticity in the stamens of flowers, must be partly due to the spiral structure of the organs in which the contractions take place, chiefly, however, to the very frequent articulations of which these parts, so mobile and so irritable, are essentially composed."

Hedwig had in these years opened the way to the knowledge of mosses; and Cirillo again observed cases of irritability and elasticity in the capsules of mosses and in the filaments they contain, the articulated structure and the spiral form of which again confirmed his opinion on the mechanism of plant movement.[3]

In studying the sensitive plant, Cirillo points out the enlargement at the insertion of each leaf; and observing what he believed to be a spiral structure within this "tubercle-like body," suspects a connection between the spiral structure and leaf-movement. Comparing the *Mimosa pudica* with the *Mimosa glauca*, Cirillo finds that the great difference in their sensitiveness corresponds with the different size and development of the articulations containing the spiral structure. This *spiral structure* corresponds, of course, with the fibro-vascular bundle inside the *pulvinus*, the motor organ, in which, as we now know, the sap tension suddenly sinks at every cause of irritation.[4]

Following the ideas of Haller, the first to have a notion of protoplasm as the physical basis of life, Cirillo believes that the seat of irritability and of life, both in animals and in plants, must be in mucilaginous substances. Thus he points out that in plants "glutinous principles" are commonly met with which must be the seat of motion, of contraction, and of irritability. Curiously enough, as an example of this glutinous principle, Cirillo gives the "elastic resin now used so extensively" extracted from the sap of *Jatropha elastica*, and existing, as he observes, in many other plants. In that time, when only impure rubber was in commerce, it had been observed that this substance, besides strongly-smelling empyrheumatic products, yielded ammonia by distillation; it was therefore generally considered of the same nature as glutinous animal substances.[5]

1 Fr. Bartolozzi, "Sopra la qualità che hanno fiori della pianta detta Apocynum Androsæmifolium di prendere le mosche, con una osservazione nuova sulla fecondazione delle piante," Opuscoli Scelti ii. (Milano, 1779, p. 103; and iv. 1781, p. 73).

2 Besides G. B. Dal Covolo, "Discorso della irritabilità di alcuni fiori, nuovamente scoperta" (Firenze, 1764), compare with the observations of contemporary botanists—G. E. Smith in England, and Des Fontaines in France. An abridgment of these observations was published in Italian at Milan: Des Fontaines, "Sull' Irritabilità degli organi sessuali di molte piante," Opuscoli Scelti x. 1787, p. 417; G. G. Smith, "Sopra la irritabilità dei vegetabili," Op. Scelt. xi. 1788, p. 379.

3 See also Antonio Barba, "Osservazioni sopra la generazione dei Muschi," Op. Scelt. v. 1782, p. 128. Barba was a pupil of Cirillo and of Della Torre.

4 See also Andrea Comparetti, "Nouvelles Recherches sur la Structure organisée relativement à la cause des mouvements de la sensitive commune". (*Mém. Acad. de Turin*, 1790).

5 It is interesting to remember that in those days, in London, Tiberio Cavallo was first beginning to prepare india-rubber tubing for scientific use, the tubes being made from an ethereal solution of the india-rubber. See Faujas St. Fond, "Su alcune arti utili, tratte da un viaggio in Inghilterra, in Scozia, e alle Isole Ebridi," Op. Scelt. xx. 1797, p. 60.

For the first applications of india-rubber in making waterproof cloth, &c., and for a description of Grossard's method of making india-rubber tubes, see Cervantes, "Resina Elastica," Op. Scelt. xxi. 1798, p. 97.

The researches of Hunter, showing the connection between nerve-action and electricity in the torpedo, and the experiments that Cirillo's friend Italisckhi was making in Naples on the electrical organ of the torpedo, brought Cirillo to believe that there must be some special connection between electricity and the action of nerves, and in general with all manifestations of irritability. As is well known, that was an active period of research on the torpedo: suffice it to record the names of Walsh, Pringle, Spallanzani, Soave. At Naples, in 1784, Domenico Cotugno accidentally received an electric shock in vivisecting a young mouse: this on the eve of Luigi Galvani's discoveries in animal electricity. This was also the period of greater fervour in experimenting upon the influence of electricity on vegetation. These experiments were chiefly carried out by Achard in Germany, Berthelon in France, Toaldo, Gardini and Vassalli in Italy and by Ingen-Housz in England. Vassalli and Rossi were soon to show the excitability of the sensitive plant under electric action.[1]

The connection of the chemical action of atmospheric air with respiration, and with all forms of animal and vegetable motion, was evidently in the mind of Cirillo. Indeed, for many years scientific research in Italy, both on animal and vegetable life, had been discovering more and more this connection, preparing the way to modern knowledge of respiration and of the origin of vital heat and of vital motion.

Fracassati, in 1665, had observed the change of colour in blood when shaken up in air. The experiments of John Mayow, the pre-discoverer, if the term may be used, of oxygen, were perhaps better known and appreciated in Italy than in England, through Ludovico Barbieri, of Imola, who translated and extended the work of the English chemist. Barbieri observed that the bright colour of arterial blood must be due to impregnation with nitro-aërial spirit; and he showed, by experiments on the transfusion of blood into an animal prevented from breathing, the truth of Mayow's teaching, that atmospheric nitro-aërial spirit, fixed in the blood, sustains life and, as in the case of the flame, produces heat. Barbieri also taught that the nitro-aërial spirit of the air causes the germination of seeds and sustains the life of plants.[2]

Hales, during the first part of the eighteenth century, had shown how plants suffer when enclosed in gases other than air, as the "air" extracted by distillation from Newcastle coal. Bonnet and Duhamel observed subsequently that leaves perish when covered with oil. But to Buonaventura Corti, the discoverer of protoplasmatic movements in the vegetable cell, is due the first exact proof of respiration in plants. Corti showed, in a series of experiments, that when air is excluded from the vegetable cell all circulation of the cell-sap is arrested: "now that we have shown," he observes, "that the circulation of the sap of the Chara is arrested when *in vacuo*, we readily understand why all plants perish without air, and why seeds cannot germinate without air, or perish shortly after sprouting."[3] In those days, in 1773, Francesco Cigna, in Turin, was again proving the action of air upon the colour of blood, and the influence of blood upon the properties of air. Cigna's experiments were repeated with greater exactitude, after the discovery of vital air, by Priestley, who showed that vital air, *i.e.* oxygen, causes the blood to brighten, while its colour deadens in contact with other gases. The discoveries of Priestley were followed, in 1779, by Adair Crawford's theory and experiments on respiration and animal heat.[4] According to Crawford, the latent heat of atmospheric air gradually becomes perceptible as animal heat, while the air absorbed through the lungs gets mixed and retained in the blood, which yields its phlogiston to the atmosphere. Crawford held that vegetable matter is elaborated, and becomes charged with phlogiston, under the action of solar rays; whilst during the combustion of vegetable matter phlogiston is again yielded up to the atmosphere and fire generated, in the same way blood generates heat, while phlogisticating expired air. Vegetables again, growing under the influence

1 Cotugno's observations on the electrical mouse are described in a letter to Vivenzio. See Tiberio Cavallo, "Teoria e Pratica dell' Elettricità Medica" (Napoli, 1784, p. 157). This is an Italian translation by Vivenzio; the original English work was published by Cavallo in London, in 1780.

2 "Planta a spiritu nitro-aereo prima vitæ stamina suscipit," wrote Barbieri in 1680. See Salvigni, "Ragionamento sopra alcune dottrine chimiche di Giovanni Mayow e di Ludovico Barbieri" (Bologna, 1816).

3 B. Corti, "Osservazioni microscopiche sulla Tremella e sulla circolazione del fluido in una pianta acquajuola" (Lucca, 1784, p. 191).

4 An Italian abridgment of Crawford's paper was published very soon after its appearance in England: Adair Crawford, "Sul calore animale e sull' infiammazione dei corpi combustibili," Opuscoli Scelti iii. 1780, p. 73.

of light, separate phlogiston from the tainted air, and repristinate in the atmosphere the power of generating heat by combustion or by respiration. A cycle of the principles of heat and of phlogiston is thus maintained through atmospheric air between the vegetable and animal kingdoms. Substituting the old conception of phlogiston by the modern idea of energy, we perceive in Crawford's theory the germ of the theory of the preservation and transformation of energy. Crawford's work prepared the way, as Carradori pointed out in 1792, to Lavoisier's experiments on respiration, and for the ready acceptance of his theory.

In Italy, where the experiments of Marsiglio Landriani, of Pietro Moscati and of Lazzaro Spallanzani, were then showing the influence of different gases on cutaneous respiration, and where Spallanzani was demonstrating the evolution of fixed air even from tissues separated from the living body, and in organisms prevented from absorbing free vital air, the theory of Crawford was readily accepted, and served as a starting-point to the experiments of Michele Rosa in Modena. Rosa, indeed, followed directly in the track opened by Ludovico Barbieri a century before. By a numerous series of experiments in transferring arterial blood into animals prepared by copious bleeding, and by the different comportment of arterial and venous blood *in vacuo*, Rosa showed that the vital principle has its seat chiefly in the blood, and is maintained by the continuous action of atmospheric air during respiration, being due to the same cause that maintains combustion. Rosa's work has not been sufficiently appreciated because of his misapplication of names, and was too soon forgotten in the great light shed by the experiments of Lavoisier; but there is no doubt that to Rosa is due the first demonstration of the incorporation of oxygen in the blood, of the special labile condition of its combination, and of the supreme importance of aëration for the vitality of all animal tissues.[1]

When Cirillo wrote his essays, the theories of Crawford and of Rosa were in their bloom, and were warmly espoused by the Neapolitan naturalist. Cirillo believed that all life, animal and vegetable, had its origin in the action of air upon the "glutinous principle," that is, the basis of life in all tissues, and that light, electricity and heat, but especially solar light, are all connected with the quickening of life. Like Lavoisier, Cirillo looked upon sunlight as the origin of all life: "Sunlight," he wrote, "the only, the inexhaustible, primitive and incomprehensible fount that pours heat and motion and life upon our globe."

John Hill, in his letter to Linnæus in 1753, had shown the special connection of light, independently of heat, with the sleep-movements of plants. Priestley's celebrated experiments on the purifying action of vegetation upon air vitiated by respiration, or by combustion, had been known since 1772. In 1779 Ingen-Housz pointed out that this action of plant-life is due to sunlight, and only takes place when light acts upon green plants. Cirillo himself must have observed the attraction of lower organisms towards light, similar to those swarm-spore movements that shortly after were first described by Giuseppe Olivi.[2] "Why," asks Cirillo, "do all polyps love light, so that, on darkening the vase in which they are contained, leaving free only a tiny hole, they all forsake darkness, and throng near the spot where they can enjoy the immediate action of the solar rays? Why are all marine animals so filled with a luminous vapour, emitting phosphoric light? Why are the most irritable fish phosphorescent and electric? Why do plants, when deprived of solar light, lose colour, aroma and robustness?" Cirillo, like most of the writers of his time, was not clear in the distinction between light and heat; but what is predominant in his mind is that all movement, both in animals and in plants, is due to fixation of vital air, to oxidation, and that light therefore, by causing the sleep-movements in plants, must be connected with some process of oxidation.

While Cirillo was writing, Senebier had already shown (1788) that the chief action of light in plants is the reverse of oxidation, causing the decomposition of carbonic acid and the evolution of oxygen. The importance of this discovery, and the mistaken notions about plant-respiration, caused what may be called the minor functions of light in plants to be neglected. Only long after the days of Cirillo and of Senebier, in the latter part of our century, investigations began on the influence of light in respiratory processes: in the decomposition of chlorophyll, in changing the composition of the sap, and the distribution of osmotic tension, and consequently in causing the movement of plant-organs, as in the case of nyctitropic and heliotropic movements. These changes are promoted, as was first shown by Michelangelo Poggioli in 1817, by the more refrangible rays of the spectrum, by those rays, namely, that are specially active in causing the oxidation of organic compounds and in decomposing silver and other salts.

Cirillo's opinions on the chemical activity of solar rays were due to his own original observations on the chemical action of sunlight upon silver chloride. His experiments were made to test the truth of an assertion by Nicola Andria that certain Ischia waters contained phlogisticated alkali (yellow prussiate), and could consequently produce Prussian blue.[1] "A curious phenomenon," Cirillo writes, "has been recently observed by me whilst analysing the Olmitello water of the Island of Ischia. Investigations of our chemists had brought them to believe that this water contained a phlogisticated alkali, similar to that prepared from the colouring matter of Berlin blue; for, on mixing the water with some *luna cornea*, or with a solution of silver in nitrous acid, not only was a white substance instantly produced, but after a short time it changed to a very beautiful and dark azure colour. This experiment, seeming to show the existence of a phlogisticated alkali in the Olmitello water, having been accidentally repeated by me towards evening, I observed that the mixture remained white during the whole night, becoming azure only on the following morning, after the rising of the sun. I also noted that the intensity of the azure colour in the sediment increased with the growing intensity of sunlight. These results led me to repeat the experiment while excluding all action of light. To half a glass of Olmitello water I therefore added a few drops of the solution of silver in nitrous acid; and as soon as the white precipitate due to the alkali was formed, I shut the glass in a place utterly impenetrable to light. For many days the precipitate remained white; but on exposure to light it became cerulean in a few minutes. The same change was observed in a water from Calabria; for, on treating it as the Olmitello water, it also rendered blue the *luna cornea*. Also our common waters, probably charged with an alkaline earth, undergo the same change. I am aware of what recent writers have said about the repristination of metals by solar heat; nor do I ignore how with a burning lens the illustrious Priestley, heating inflammable air in contact with minium inside a glass vessel, was able to repristinate lead. But my experiment will serve at least to correct the error of those who analysed the Olmitello water, believing it to contain a phlogisticated alkali, similar to the Prussian alkali; and secondly, this experiment gives us a sure proof of the energy of solar rays in repristinating metals. These observations, although having a distant connection with the movements and irritability of vegetables, are also worthy of record in connection with other considerations which I hope shortly to publish."

Cirillo's essay was published, in its first edition, in 1789, so that the Olmitello experiments must have been made shortly before that year and after Andria's last publication of 1783. As is well known, the experiments of Scheele (not counting the earlier, forgotten experiments of J. H. Schultze in 1727) were published in Swedish in 1777; a French translation, by Baron Dietrich, of Scheele's treatise on Air and Fire appeared in Paris in 1781.[2] Scheele's experiments on *luna cornea* and other silver salts are quoted and commented upon by Felice Fontana in 1783.[3] Senebier, in 1782, had been experimenting on the rapidity of action of different lights upon silver chloride.[4] Cirillo therefore ought to have been acquainted with Scheele's experiments, although there is every reason to believe that he, generally so precise in recording previous work, was not aware that, only a few years before his own experiments with the Ischia water, the action of light upon silver salts, and especially

the action of the more refractive rays of the spectrum, had been demonstrated and studied by the highest chemical investigator of the time, who had died in 1786. Cirillo's observations are, however, worth recording, because they were connected in his mind with the action of sunlight in causing movements and irritability in vegetable organs.

Other workers in those days were investigating in Italy the chemical action of light; and their experiments, like those of Cirillo, are also generally forgotten. In 1782, Alessandro Barca, in Padua, studied the effect of solar rays in accelerating the decomposition of phlogisticated alkali, or yellow prussiate, in the presence of acetic acid.[1] In 1794, Anton Maria Vassalli, in Turin, in comparing the action of solar and of artificial light, showed that the latter darkens silver salts, causes chlorotic leaves to become green, rouses the sleeping leaves of the sensitive plant, and acts generally in the same manner, although with less intensity, as the light of the sun. Vassalli observed a diminution in weight in the silver chloride darkened by light; he also experimented upon the effect of moonlight upon this salt, and upon vegetation.[2]

The "Discorsi Accademici" of Cirillo, in which are the two remarkable essays, "Del moto e della irritabilità dei vegetabili" and "La cagione della vita," were first published in 1789, and re-edited in 1799. This second edition was the last scientific labour of Cirillo, for in that same year he was overwhelmed in the political storms that swept over Naples. All the writings of Cirillo glow with warm philanthropy and patriotism, and we see in them a constant protest against the prejudices and superstitions then so high in authority in the Neapolitan kingdom. After the cowardly flight of King Ferdinand from Naples in December 1798, leaving the city a prey to royalist anarchy, Cirillo joined with the patriots who favoured the entrance of the French into Naples and the establishment of the Parthenopæan Republic. Pressed by the insistance of his friends, Cirillo accepted the presidency of the legislative body, but during the brief period of his political power he occupied himself mainly in alleviating the growing misery of the people; above all, Cirillo remained the philanthropist and the physician rather than the politician. The Republic lasted a few months, sinking finally in the struggle with the brigand hordes of the Holy Faith, that through pillage and bloodshed Cardinal Ruffo led from Calabria to Naples. Cirillo was among the many who capitulated in the Castles of Naples, on condition of a free passage to a French port. The sorrowful history of what followed is well known, of how the capitulation was ruthlessly broken when Castles and prisoners were secured. All those who had held office under the Republic, or had any direct connection with its government, were condemned to death for high treason. From June 29, 1799, to September 1800, execution followed execution, until in Naples alone ninety-nine of the foremost men were put to death, besides the many—it is said 300—executed in the provinces. Domenico Cirillo was hanged on the same day as Mario Pagano and the poet Ignazio Ciaja. "For the death of these men all the city mourned," wrote Marinelli, a diarist of the time. Another botanist, Abate Nicola Pacifico, an old man of seventy, companion and fellow-worker of Cirillo, shared his fate on August 20, on the same day when the gifted Eleonora Fonseca Pimentel was delivered to the hangman.

Cirillo's house was pillaged by the mob, and his collections and books, among which was the herbarium of Imperato, were burned or dispersed. "Let the idle and ignorant know that love of humanity, zeal for science, and faithfulness to duty can only be quenched in me with my life"—thus wrote Cirillo in the days of his prosperity, little dreaming of the distant purport of his words. Nobly indeed, when oppression and ignorance prevailed, in the days of suffering and agony, Cirillo to the very last kept faith to duty and to Fatherland. ITALO GIGLIOLI.

METALLIFEROUS DEPOSITS.

A COURSE of four Cantor Lectures delivered before the Society of Arts by Mr. Bennett H. Brough, on the nature and yield of metalliferous deposits, has just been published. Descriptions are given of the principal ore deposits of the world, and the statistics of production appended furnish a clear idea of the condition of the mining industry at the present time. The subject is of great importance from a commercial point of view, as will be evident from a moment's consideration of the enormous value of mineral resources. In the United Kingdom alone, the value of the minerals raised in one year has approached 80,000,000*l.*; and the vast sums representing the British capital invested in mines in all parts of the world will be readily appreciated. Last year, the number of new mining companies registered in Great Britain was 559, with a united nominal capital of 71,687,366*l.* Of these companies, 281, with a nominal capital of 37,037,057*l.*, were formed to mine and explore in British colonies and dependencies, and 157, with a nominal capital of 24,049,502*l.*, to mine in foreign countries. During the present century the mining industry has made remarkable strides. Some indication of the progress made, even during the past ten years, is afforded by a comparison of the world's output of metals in 1889 and in 1898. In round numbers, the production of the principal metals was as follows:—

	1889. Tons.	1898. Tons.	Value of output in 1898. £
Pig-iron	26,000,000	36,000,000	100,000,000
Gold	182	430	57,500,000
Silver	3,900	6,000	24,000,000
Copper	266,000	431,000	21,750,000
Lead	549,000	770,000	10,000,000
Zinc	335,000	468,000	9,950,000
Tin	55,000	77,000	8,000,000
Antimony	11,000	28,000	1,100,000
Mercury	3,838	4,100	815,000
Nickel	1,830	6,200	725,000
Aluminium	70	4,000	440,000

The simplest classification of the ore deposits from which these vast outputs have been obtained, divides them into (1) beds, (2) veins, and (3) masses. This classification has proved well adapted for practical use. The more elaborate systems of classification that have from time to time been proposed are fully discussed, the classifications dealt with being those of Agricola (1555), Burat (1855), B. von Cotta (1853), Grimm (1869), J. A. Phillips (1884), A. von Groddeck (1878), F. Pošepný (1880), Sir A. Geikie (1882), H. S. Monroe (1892), H. F. Kemp (1892), H. Louis (1896), H. Hoefer (1897) and G. Gürich (1899). The last-named investigator uses the mode of concentration as the basis of classification. The concentration may take place with or without a change in the state of aggregation. In the former case the passage into the solid state is from a state of vapour, from a molten state, or from a state of aqueous solution. Consequently the following classes of ore deposits are distinguished:—

I. Sublimation deposits: (*a*) syngenetic, in which the sublimation of the vapours takes place simultaneously with the solidification and within a solidifying magma, *e.g.* tin ore deposits; (*b*) epigenetic, in which crusts are formed coating fissures; (*c*) metagenetic, in which the constituents of a rock are dissolved by pneumatolysis and replaced by metallic substances.

II. Magmatic, or solidifying deposits: (*a*) syngenetic, representing the usual form of magmatic deposit as described by Vogt; (*b*) epigenetic, only imaginable if an apophysis of a magma within the enclosing rock consists of a metallic band; (*c*) metagenetic, hardly imaginable.

III. Precipitation deposits: (*a*) syngenetic, in which the chemical precipitation takes place simultaneously with the sedimentation, the deposit being formed simultaneously with the surrounding rock, *e.g.* seams, beds; (*b*) diagenetic, in which the concentration takes place in the muddy floor of a lake, *e.g.* concretionary nodules of clay iron ore; (*c*) epigenetic, in which the deposit is formed subsequently to the surrounding rock, *e.g.* veins, cave fillings; (*d*) metagenetic, in which the soluble constituents of a rock are dissolved, transported, and the metallic substance precipitated, the deposit being formed subsequently to the enclosing rock, but growing at the expense of the latter.

IV. Separation deposits: (*a*) residual deposits formed by chemical concentration, a soluble rock constituent, *e.g.* lime, being carried away, and a metallic substance, *e.g.* brown iron ore, remaining unaltered; (*b*) detrital deposits formed by mechanical concentration, *e.g.* dry placers, alluvial deposits.

In view of the apparent impossibility of definitely determining the genesis of a given deposit, it may be questioned how far it is advisable to adopt a genetic classification. Probably, however, by employing that system of classification, an observer would be induced to make a more thorough examination than if he were

required merely to define the deposit by its outward form. Any efforts to introduce improvements in mining must, however, subordinate theory to practical requirements.

In consequence of the difference of form in beds, veins and masses, various methods of working have to be employed. Underground mining is not necessary with all ore deposits. The iron ore beds of Northampton, for example, and the alluvial beds of river gravel containing gold are worked open-cast.

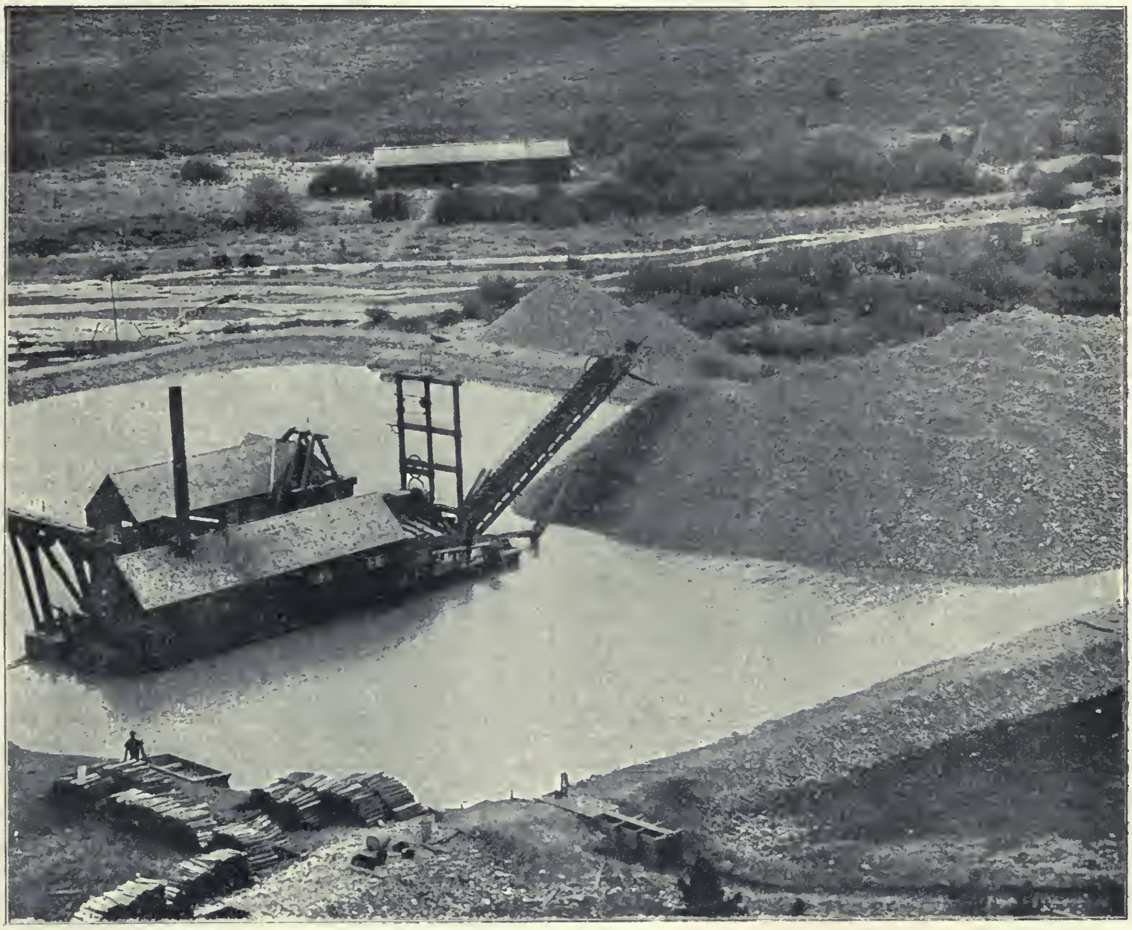

FIG. 1.—Gold Dredge at work excavating auriferous Gravel 45 feet below the Water Surface.

Of late years very successful results have been obtained by extracting auriferous gravels from the beds of rivers by dredges. The practice of dredging originated and has been brought to its present state of perfection on the Clutha river, in the province of Otago, New Zealand. Ground containing only a grain or a grain and a half of gold per cubic yard can now be worked at a profit. The remarkable yield of a dredge working at Cromwell, on the Clutha river, which cost 5,000*l*. to build and launch, and obtained more than that amount of gold within seven weeks after starting, shows how quickly the capital sunk in the industry has, in some instances, been returned. Experience in Montana, United States, shows that with a bucket-dredge 98 per cent. of the gold in the gravel is extracted. The cost of dredging when steam is employed is $4\frac{1}{2}$*d*. per cubic yard, and when electricity is employed for power $2\frac{1}{4}$*d*. per cubic yard. The practice of dredging is coming into increasing use in New Zealand, Canada, California, Montana, the Republic of Colombia, and elsewhere. It represents an important advance in the working of alluvial deposits, and if the yields of gold in the future are not likely to be so sensational, they will probably be more regular than they have been in the past. The accompanying illustration (Fig. 1) shows the latest type of gold dredge made by the Risdon Ironworks of San Francisco. As represented, it is excavating auriferous gravel 45 feet below the water, and stacking it 24 feet above.

The gradual increase in the world's annual production of gold is shown in the accompanying diagram (Fig. 2).

The value of the world's gold production in 1898 was 57,500,000*l*., of which the Transvaal produced 27·6 per cent., Australasia 22·5 per cent., the United States 22·1 per cent., Russia 8·8 per cent., Canada 4·8 per cent., Mexico 3 per cent., India 2·7 per cent., and China 2·1 per cent. Thus the Transvaal, Australasia, and the United States together produced 72 per cent. of the total. The production last year was even greater, amounting probably to 62,700,000*l*., notwithstanding

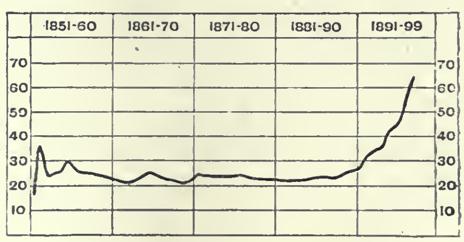

FIG. 2.—World's gold production (in millions of pounds).

the interruption in Transvaal mining. From the present condition and prospects of the more important mines in Africa, Australasia, the United States, Canada and other countries, it seems that there are no signs of falling off in the world's gold

production. In the case of silver, of which the world in 1898 produced 165,000,000 ounces, Mexico produced 34·4 per cent., the United States 33 per cent., and Australasia 7·3 per cent. Less than half the world's supply was obtained from silver ores. The remainder was obtained from the metallurgical treatment of other ores in which silver was an accessory constituent. Since those ores would continue to be mined for the other metals they contained, a steady supply of silver was assured, whilst a slight rise in the price of silver would enable many deposits of true silver ores now untouched to be worked.

In a paper read before the Society of Arts in 1854, Mr. J. K. Blackwell stated that the world's production of pig iron then amounted to 6,000,000 tons. Of that quantity the United Kingdom produced 50 per cent., France 12·5 per cent., the United States 12·5 per cent., and Germany 6·6 per cent. In 1898 the world's production had risen to 35,741,000 tons, of which the United States produced 32·7 per cent., the United Kingdom 24·1 per cent., Germany 20·6 per cent., and France 7·1 per cent. The relative position of the different countries from a mining point of view is better shown by the statistics of iron ore production. The world's production in 1898 was 73,670,000 tons, of which the United States produced 26·2 per cent., Germany 21·6 per cent., the United Kingdom 19·3 per cent., Spain 9·7 per cent., France 6·2 per cent., Russia 5·6 per cent., Austria-Hungary 4·5 per cent., and Sweden 3·1 per cent. The more important iron ore deposits now worked are at the mines of Lake Superior, Bilbao, Southern Spain, the Ural, Styria, Dannemora, Grängesberg and Gellivare.

With regard to copper, the rapid decadence of British copper mining was owing to copper in the Cornish mines having given place to tin as greater depths were reached, and to these great depths and the quantity of water encountered rendering competition with the American and Spanish deposits impossible. There are, however, large areas unexplored, and many mines worth re-opening should the price of copper rise, and should the disadvantages experienced in Great Britain make themselves felt abroad. Owing to the increased demand for copper caused by the rapid extension of the applications of electricity, a further rise in price is not improbable. The world's production of copper in 1898 was 424,126 tons, of which amount the United States produced 55·1 per cent., Spain and Portugal 12·6 per cent., Japan 5·9 per cent., Chili 5·8 per cent., Germany 4·9 per cent., Australasia 4·2 per cent., Mexico 2·5 per cent., Canada 1·9 per cent., Cape Colony 1·6 per cent., and Russia 1·4 per cent. Last year the world's copper production was about 474,000 tons. The Anaconda Mine produced 11 per cent. of the world's output, and among other important copper mines are those in Arizona, in the Lake Superior district, in the South of Spain (Rio Tinto and Tharsis), and Portugal (San Domingos), in South America, in Japan; at Mansfeld, and at the Rammelsberg, in Germany; at Falun, in Sweden; and in Australasia (Mount Lyell, Tasmania; Moonta and Walleroo, South Australia; and Great Cobar, New South Wales).

CONFERENCE OF DELEGATES OF CORRESPONDING SOCIETIES OF THE BRITISH ASSOCIATION.

THE first meeting of the Conference took place at Bradford on Thursday, September 6.

The report of the Committee, a copy of which was in the hands of every delegate present, was taken as read. The chairman then remarked that the chief subject for discussion that day consisted of the following resolutions, which had been brought forward by the Yorkshire Naturalists' Union:—

(1) That the Conference of Delegates be allowed to meet on the first day of the British Association meeting, and make their own arrangements for subsequent meetings and order of business.

(2) That it is desirable, in order to make the discussions of the Conference of Delegates more useful to the local societies, that they should have the power of deciding the subjects for discussion at the meetings of the Conference, and it is suggested, therefore, that a circular be sent by the Committee every year to each of the corresponding societies asking them to send a list of subjects for discussion (not more than two or three) at the forthcoming meetings. The Committee then to send to the corresponding societies a schedule containing the titles of all the subjects proposed for discussion, asking each society to mark such of these subjects as it deems most desirable to discuss at the Conference meetings. On receipt of this information the Committee will then arrange the list of subjects in order of precedence as indicated by the support given to each subject by the societies; and a copy of this should be sent to the delegates or Societies as an agenda paper before the first meeting of the delegates.

After a long discussion, it was resolved that the meetings of the Conference be held on Thursday and Tuesday, as heretofore.

Copyright.—Mr. Walton Brown remarked that some time ago Lord Monkswell had introduced a Bill into Parliament dealing with copyright, but so far as scientific societies were concerned the Bill ignored some important points. There was no provision that a society should have any copyright in the publication of its own transactions. He believed that societies could claim copyright if they paid their contributors. He thought that the Conference should ask the Corresponding Societies Committee to take steps to have an amendment proposed recognising the copyright of scientific societies in their publications.

Prof. Henry Louis pointed out that the British Association expressly disclaimed copyright for themselves; and the Rev. J. O. Bevan urged that a special case should be prepared and submitted to counsel for a legal opinion. Mr. Walton Brown's views were unanimously accepted by the meeting, which then adjourned.

At the second meeting of the Conference an address on dew-ponds was given by Prof. Miall. In the first place, Prof. Miall noticed the mention of dew-ponds by Gilbert White ("Natural History of Selborne," Letter lxxi.), and more recently by the Rev. J. C. Clutterbuck in a prize essay on "Water Supply." Both writers described them as existing on the tops of chalk hills, and Mr. Clutterbuck says that at the selected spot an excavation is made from 30 to 40 feet or more in diameter, and from 4 to 6 feet deep. The bottom is covered with clay mixed with lime, and a layer of broken chalk is placed over the clay with lime to prevent injury to this impermeable lining. Water is then introduced by artificial means. If there is a fall of snow this is collected and piled in the pond. Ponds so made have been known never to become dry during periods of twenty or thirty years. They are most common on the chalk hills of Sussex and Hampshire, and are also found in Berkshire and Wiltshire. But on the chalk of Hertfordshire, Bedfordshire, Lincolnshire and Yorkshire there are few or none.

As dew-ponds often occupy the summit of a ridge so precisely that they can have no collecting ground worth mentioning, and as any springs are hundreds of feet below, it becomes an interesting question why they retain more or less water when the low-level ponds of the same district have become dry, though they supply water for large flocks of sheep.

Prof. Miall then reviewed the evidence bearing upon the question whether these ponds are mainly dew-ponds or rain-ponds, and quoted the experience of Mr. Clement Reid, who found that at the end of a long drought the best dew-ponds were sheltered on the south-west side by an overhanging tree, or the hollow was sufficiently deep for the south bank to cut off much of the sun. The depth or shallowness of the water did not appear to make so great a difference as might be expected.

It was, however, evident that many additional observations were necessary before this question could be settled. It was desirable that the temperature of the water of the pond at various depths, as taken hourly through a summer night, should be noted, and that many other thermometrical observations should be made. He concluded by asking that residents in the south-eastern counties would investigate the matter.

Mr. Clement Reid had been working for some years in a country where dew-ponds were abundant, but did not think they were formed in the scientific manner pretended by their makers. In times of drought some dried up and others did not, the fittest surviving. Farmers were continually making new ones, and sometimes, by accident, hit on a satisfactory site It was unfortunate that they were almost entirely without meteorological observations on the high ground where dew-ponds might be seen.

Mr. Hopkinson noted the difficulty of ascertaining the amount of water contributed to the pond by dew. A distinction must be drawn between dew and mist. There were scarcely any rain gauges on the high ground where dew-ponds existed, though probably more rain fell there than in the valleys. He did not know of any dew-ponds in Hertfordshire. Mr. J. Brown and Mr. W. Gray stated that there were no dew-ponds in Ire-

land. Mr. W. M. Watts considered that the amount of dew could hardly exceed $1\frac{1}{2}$ inches per annum, and Mr. Barrowman was not aware of the existence of dew-ponds in Scotland. Mr. G. P. Hughes said that dew-ponds were unknown in his district (Berwickshire). He thought they might prove useful in Australia and South Africa, dry countries where the dews were heavy. The Rev. E. P. Knubley noted their existence in Wiltshire, and Prof. H. Louis thought that the exact composition of the water in these ponds was one of the essential points to be examined. Prof. Potter noted the existence of ponds in Warwickshire, Suffolk and the South of Portugal, which he thought might prove analogous to dew-ponds.

Prof. Miall referred to various points which had been raised in the discussion. Ponds to be classed with dew-ponds must not be fed by springs or surface drainage. He had hitherto found that ponds in the Midland counties, supposed to be analogous to dew-ponds, were not really so. He hoped that the corresponding societies would take up the subject.

Section C.—Mr. Monckton, representing Section C, drew attention to the labours of two committees wishing to obtain the co-operation of the corresponding societies in their work, the Geological Photographs Committee and the Erratic Blocks Committee. The secretary of the Geological Photographs Committee was Prof. W. W. Watts; the secretary of the Erratic Blocks Committee Prof. P. F. Kendall.

Section D.—The Rev. E. P. Knubley, representing Section D, was anxious that the corresponding societies should go on observing the migration of birds; also the food-supply of birds and the life-histories of insects.

Section H.—Mr. E. Sidney Hartland, representing Section H, brought before the Conference the work of the Anthropological Photographs Committee. That committee wished to collect photographs of objects of anthropological interest which were now scattered over the country, and almost unknown outside their own localities. They wanted photographs of prehistoric stone monuments and implements, of primitive pottery and of objects connected with local superstitions. The collection would be placed in the rooms of the Anthropological Institute. The secretary of the committee was Mr. J. L. Myres.

The Rev. J. O. Bevan urged the committees of the corresponding societies to lay before their members the desirability of a systematic survey of their counties with respect to their ethnography and ethnology, archæology, folklore, meteorology, botany, ornithology, &c. This kind of work was being done in part at various places. The committee of the British Association which had been concerned with ethnography and ethnology had been dissolved at the Dover meeting. He hoped that the local societies would take up the work, and inform the Corresponding Societies Committee what was being done.

After a few remarks from Mr. Hembry, who suggested that at future meetings sectional matters should be taken before the reading of a paper on any special subject, the meeting came to an end.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Vice-Chancellor announces that Mr. W. W. Astor has contributed the sum of £10,000 to the University Benefaction Fund.

Mr. F. G. Kenyon, assistant keeper of the manuscripts in the British Museum, has been appointed Sandars Reader in bibliography.

Dr. Haddon, F.R.S., has been appointed University lecturer in ethnology, and Mr. J. J. Lister, F.R.S., to be demonstrator of comparative anatomy.

A University lectureship in experimental physics is vacant by the resignation of Prof. Wilberforce. Applications should reach the Vice-Chancellor by Saturday, November 3.

The portrait of Charles Darwin, now in the Philosophical Library, has been lent for the exhibition of the works of Sir W. B. Richmond, to be held in the New Gallery.

MR. J. A. MCCLELLAND, M.A., has been appointed to the chair of Natural Philosophy in the University College, Dublin, which was rendered vacant by the death of Prof. Preston. Mr. McClelland is a native of North Ireland, and studied physics under Prof. Anderson at Queen's College, Galway. After graduating M.A., he went to Cambridge and continued his studies in physics under Prof. J. J. Thomson, obtaining the B.A. (Research) degree for his original work in the Cavendish Laboratory. In Ireland Mr. McClelland gained an "1837 Exhibition" Science Scholarship, and later a Junior Fellowship of the Royal University of Ireland.

A NOTEWORTHY announcement in the Calendar of University College, Bristol, is that a clinical and bacteriological research laboratory has been established at the college, under the direction of Prof. A. F. Stanley Kent. The value of such a laboratory in a port like that of Bristol cannot be over-estimated, and the City authorities should show their appreciation of it in a practical way. The laboratory will not only provide a means of obtaining trustworthy information and reports upon pathological material, but will also give medical men an opportunity of carrying out bacteriological investigations. Should plague ever appear in Bristol, as it has done at Glasgow, the City authorities will know the value of the laboratory now established at their University College. At present the college does not receive nearly so much local support as some of the other provincial colleges, and there seems to be little hope that there will ever be a West of England University with its centre at Bristol, analogous to the University of Birmingham.

IN the course of her able and suggestive address at the opening of the Passmore Edwards Museum of the Essex Field Club on October 18, the Countess of Warwick made the following statement with respect to local museums:—"I am convinced that museums are destined to play such an important part in education in the future that no town of any importance will be able to be without an institution of this kind. But one of the chief reasons why this part of the club's work has not hitherto been practically realised is because the establishment and maintenance of a museum requires considerable financial resources. However zealous the members of a county natural history society may be, their aims and objects rarely rouse popular enthusiasm to the extent of raising an adequate fund for such purposes. In some counties private munificence had compensated for the lack of public interest. In other cases—and I am glad to be able to quote as an example another Essex town, Colchester—an enlightened Town Council has enabled a local museum to find an appropriate home. And again, in other instances, some of the County Councils have given financial aid from the Technical Instruction Grant, quite a legitimate expenditure as it appears to me, and, if I may express a personal opinion, a most valuable way of assisting in the spread of that knowledge which is the core an essence of all sound scientific education—a knowledge of nature at first hand as distinguished from the knowledge imparted through books or didactically taught in the class-room. But I am afraid that we as a nation have hardly yet risen to that high-water mark of scientific culture which should characterise a great civilisation. I do not mean to imply that we are lacking in scientific ability, that we are devoid of originality, or that we have failed to contribute our share of knowledge to the sum total of human progress. But I fear that the *spirit of modern science* has not sunk into the public mind—it has not permeated the rank and file to that extent which is required by the age in which we live, the century of science *par excellence.* Our purses are ever open, and have always been opened, in the names of charity and philanthropy, religious endowment and missionary enterprise, political organisation and popular sports. But science, upon which the national welfare and our position in the scale of nations ultimately depends, has to go begging for her tens, while thousands are forthcoming for these other objects." These remarks, which were received with loud applause by the audience at West Ham to whom they were addressed, coming from the mouth of a lady who has set such a brilliant example by her pioneering work in rural education, should be productive of good throughout the country. Most cordially will our readers endorse Lady Warwick's sentiments.

SCIENTIFIC SERIALS.

THE *Journal of the Royal Microscopical Society* for October contains a further instalment of Mr. F. W. Millett's paper on recent Foraminifera of the Malay Archipelago; a short article on a new projection eye-piece and an improved polarising eye-piece, by Mr. E. B. Stringer; and the conclusion of Mr. E. M. Nelson's note on the microscopes of Powell, Ross, and Smith, the present instalment dealing with the instruments of

Smith and Beck (now Messrs. R. and J. Beck, Ltd.). In the summary of recent researches in microscopy is an interesting description (with illustrations) of a microscope, with its oculars and objectives, used by Prof. Amici, the discoverer in 1841 of the part played by the pollen-tube in the fertilisation of flowering plants. Nothing could more forcibly illustrate the enormous advance made during the past sixty years in the manufacture of the microscope and its appliances.

Bollettino della Società Sismologica Italiana, vol. vi. 1900–1901, Nos. 2 and 3.—On the necessity and on the choice of comparable seismic apparatus, by A. Cancani (see pp. 395–6).—On the velocity of propagation of the Emilian earthquake of March 4, 1898, by G. Agamennone. The velocity is found to be about 3 km. per second, and it does not vary perceptibly with the distance from the epicentre.—Contribution to the study of the great Neapolitan earthquake of December 1857, by L. Antonio. Contains a copy of a letter written from Caggiano, close to the position assigned by Mallet to the epicentre.—New type of seismometrograph, by G. Agamennone. A reprint of a paper describing an instrument specially designed for registering the very small movements of the ground.—Notices of earthquakes recorded in Italy (March 21 to June 5, 1899), by A. Cancani, the most important being the Greek earthquakes of April 6, 15 and May 3, the Dalmatian earthquake of May 15, and distant earthquakes on March 3, April 2, 12, 13, 16, May 8 and June 5.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 21.—"On the Capacity for Heat of Water between the Freezing and Boiling Points, together with a Determination of the Mechanical Equivalent of Heat in Terms of the International Electrical Units." Experiments by the Continuous-flow Method of Calorimetry performed in the Macdonald Physical Laboratory of McGill University, Montreal. By Howard Turner Barnes, M.A.Sc., D.Sc., Joule Student. Communicated by Prof. H. L. Callendar, F.R.S.

At the Toronto meeting of the British Association in 1897, a new method of calorimetry was proposed by Prof. Callendar and the author for the determination of the specific heat of a liquid in terms of the international electrical units. At the Dover meeting in September, 1899, some of the general results obtained with the method for water over a part of the range between 0° and 100° were communicated, with a general discussion of the bearing of the experiments to the work of other observers. In the present paper the author gives a summary of the complete work, in the case of water, to determine the thermal capacity at different temperatures between the freezing and boiling points.

Theory of the Method.

If a continuous flow of liquid in a tube be made to carry off a continuously supplied quantity of heat EC, in electrical units, then after all temperature conditions have become steady

$$JsQ(\theta_1 - \theta_0)t + (\theta_1 - \theta_0)ht = ECt$$

where

J = mechanical equivalent of heat,
Q = flow of liquid per second,
s = the specific heat of the liquid,
θ_0 = the temperature of the liquid flowing into the tube,
θ_1 = the temperature of the liquid flowing out of the tube,
h = the heat loss per degree rise of temperature from the liquid flowing through,
t = the time of flow.

In the case of water, E represents the E.M.F. across an electrical heating conductor in the tube, and C the current flowing. In this case, which is treated of entirely in the present paper, Js is replaced by $4{\cdot}2\,(1 \pm \delta)$ where δ is a small quantity to be determined, and varies with the thermal capacity of the water, which is not exactly equal to 4·2 joules at all points of the range.

Substituting in the general equation, rearranging terms, and dividing through by t, the equation is given in the following form:—

$$4{\cdot}2Q(\theta_1 - \theta_0)\delta + (\theta_1 - \theta_0)h = EC - 4{\cdot}2Q(\theta_1 - \theta_0),$$

which is termed the general difference equation of the method. The two terms δ and h may be determined by using two values of Q, giving two equations of the form

$$4{\cdot}2Q_1(\theta_1 + \theta_0)\delta_1 + (\theta_1 - \theta_0)h = E_1C_1 - 4{\cdot}2Q_1(\theta_1 - \theta_0)$$
$$4{\cdot}2Q_2(\theta_2 - \theta_0)\delta_2 + (\theta_2 - \theta_0)h = E_2C_2 - 4{\cdot}2Q_2(\theta_2 - \theta_0).$$

For the same value of θ_0, if the electrical supply for the two flows is regulated so that $\theta_1 = \theta_2$, then $\delta_1 = \delta_2 = \delta$, and by eliminating h,

$$\delta = \frac{(E_1C_1 - 4{\cdot}2Q_1(\theta_1 - \theta_0)) - (E_2C_2 - 4{\cdot}2Q_2(\theta_1 - \theta_0))}{4{\cdot}2(Q_1 - Q_2)(\theta_1 - \theta_0)}$$

which corresponds to the mean temperature

$$\theta_0 + \frac{\theta_1 - \theta_0}{2},$$

where $(\theta_1 - \theta_0)$ is not too great.

In the present method the flow tube is of glass, about 2 mm. in diameter, connected to two larger tubes forming an inflow and an outflow tube, in which the temperature of the water is read, by a differential pair of platinum thermometers, before and after being heated by the electric current. A glass vacuum jacket surrounds the fine flow tube and a part of the inflow and outflow tubes, to reduce the heat loss as much as possible. A copper water jacket encloses the inflow tubes and vacuum jacket, in order to maintain the glass surface of the vacuum jacket always at a constant temperature equal to the inflowing water. The heat loss from the water is then the loss due to radiation from the flow tube through the vacuum jacket, and conduction from the ends of the flow tubes.

In testing the accuracy of the method, the dependence of the heat loss on the rise of temperature was found, and the dependence of the heat loss on the flow.

The results with different calorimeters and with different rises of temperature are given in the following table:—

Summary of the Specific Heat of Water from Smoothed Curve.

Temperature C.	δ	J.
5	+0·00250	4·2105
10	−0·00050	4·1979

90	+0·00025	4·2010
95	+0·00090	4·2038
	Mean value	4·18876

The values of δ represent the specific heat of water in terms of a thermal unit equal to 4·2000 joules, which occurs at 9° C. It is more suitable to select a thermal unit at a more convenient part of the scale. The mean value of the mechanical equivalent of heat from these measurements over the whole range is 4·18876 joules, which is very nearly equal to the value at 16° C., which is 4·1883 joules. It seems desirable to select a unit at a temperature which, if at the same time at a convenient part of the scale, may be equal to the mean value over the whole scale. The author has in consequence adopted a unit at 16° C., and has expressed the specific heat of water in terms of this unit.

Two formulæ can be fitted very accurately over the scale. Between 5° and 37·5° C. the following expression in terms of a thermal unit at 16° is found to read,

$$S = 0{\cdot}99733 + 0{\cdot}0000035(37{\cdot}5 - t)^2 + 0{\cdot}00000010(37{\cdot}5 - t^3).$$

The same formula holds between 37·5° and 55° by simply considering all values of the cubical term positive. Above 55° the simple formula

$$S = 0{\cdot}99850 + 0{\cdot}000120(t - 55^\circ) + 0{\cdot}00000025(t - 55)^2$$

holds with great accuracy.

Physical Society, October 26.—Dr. Lodge, President, in the chair.—The chairman read a letter from Prof. Cleveland Abbe, of the United States Coast and Geodetic Survey, stating that the *Monthly Weather Review* would be sent regularly to any member of the Physical Society expressing a wish to receive

it. On the other hand, the Chief of the Weather Bureau would at any time be glad to receive communications referring to the physics of the atmosphere.—Dr. Shelford Bidwell then exhibited some experiments illustrating phenomena of vision. The first phenomenon illustrated was that known as "Recurrent Vision." A vacuum tube, illuminated by an induction coil, was made to rotate about a horizontal axis, and was seen to be followed, at an angle of about forty degrees, by a feebly luminous reproduction of itself. A spot of white light, projected upon a screen, and caused to move slowly in a circular path, was also followed by a less luminous spot. The same effect was shown by spots of green and yellow light, but in the case of red light no ghost was visible. The phenomena of recurrent vision are due principally, if not entirely, to the action of violet nerve fibres. The next experiments related to the non-achromatism of the eye. The lenses of the eye do not constitute an achromatic combination, although under ordinary conditions a bright object is not surrounded by fringes of colour. The effects of chromatic aberration are disguised by the luminous haze which surrounds the object, produced by a defect in the eye regarded as an optical instrument. A six-rayed star, formed by cutting a hole in an opaque screen, was illuminated by a gauze-covered condenser containing an incandescent lamp. The star was fairly clearly defined, and there were no fringes. More attentive observation showed a luminous haze. This haze is formed in consequence of the cellular structure of the eye, and the brightest rays—orange, yellow and green—are chiefly instrumental in forming it. If, therefore, these rays are obstructed, the conditions are more favourable for the observation of chromatic aberration. The rays were consequently cut off by means of coloured glasses, and the general hue of the star was purple; to some it appeared bordered with dark blue, while to others (long-sighted) it appeared bordered with red. Two oblong patches, one red and the other blue-violet, and of approximately the same intensity, were then produced side by side upon a screen. An observer with very good eyesight was able, at a distance of ten feet, to focus the patches alternately with perfect distinctness. In general, the blue patch was said to be more or less blurred. With an achromatic eye it should be possible to focus both together. Dr. Bidwell then showed some lantern slides, illustrating the complex form seen when viewing a small luminous spot through a gauze-covered lens placed so as not to be in exact focus. Some experiments were performed illustrating the principle of the colour top. When a bright image is formed on the retina after a period of darkness it has, in general, a red border which lasts for a fraction of a second. A dark patch suddenly formed on a bright ground has a blue border which lasts for a similar time. These effects were attributed by Dr. Bidwell to a sympathetic action of the red nerve fibres. When the various nerve fibres occupying a limited portion of the retina are stimulated by ordinary white or yellow light, the immediately surrounding red nerve fibres are for a short period excited sympathetically, while the violet or blue and green fibres are not so excited, or in a much less degree. Again, when light is suddenly cut off from a patch in a bright field, there occurs a sympathetic insensitive reaction in the red fibres just outside the darkened patch, in virtue of which they cease for a moment to respond to the luminous stimulus; the green and violet fibres by continuing to respond uninterruptedly give rise to the sensation of a blue border. By a simple experiment it was shown that the explanation of the colour top, depending upon changes in the convexity of the eye and non-achromatism, was untenable. By the use of a strong light it is possible to get negative after-images after looking at a brightly-coloured object. These images are complementary in colour to the object, and are formed even if the object is only viewed for a fraction of a second. By means of proper illumination and a disc rotating at the proper speed, a red wafer was so arranged that, upon looking at it, it was impossible to recognise the wafer itself, but only the continuous green after-image. The Chairman expressed his interest in the last experiment, in which it was possible to see the negative after-image of an object and not the object itself. Prof. S. P. Thompson said these experiments threw a doubt on some of the accepted notions about the properties of the eye. Dr. Bidwell asks us to believe that the yellow haze is due to a cellular structure in the eye. Is there such a structure? Can it be observed with a microscope? And do its meshes correspond in magnitude with those necessary to produce the effects? By diminishing the size of the pupil the haze is diminished and the sharpness of the image is increased. The effects seem to be due to ordinary aberration. Prof. Thompson said that the achromatism of the eye was simply shown by covering half the object-glass of a telescope and viewing a bright object with it. The object then seems bordered with coloured fringes. Mr. Blakesley, referring to the colour patches used by Dr. Bidwell, pointed out that although the patches were the same distance from the lens, yet they did not possess the same magnification. The last experiment shown did away with the theory of persistence of vision, because the space between the object and the negative after-image was evidently not illuminated. Mr. Trotter asked if red and green were the only colours which gave complementary negative after-images. Dr. Bidwell, in reply, said the effect was obtainable throughout the length of the spectrum.—A paper on the concentration at the electrodes in a solution, with special reference to the liberation of hydrogen by electrolysis of a mixture of copper sulphate and sulphuric acid, was read by Dr. H. J. S. Sand. In this paper an equation has been derived for calculating the concentration at the electrode of a solution of a single salt from which the metal is being deposited under the conditions (1) that the solution is contained in a cylindrical vessel bounded by the electrodes, (2) that no convection-currents occur, and (3) that the diffusion of the salt obeys Fick's law, and its transport values are constant. This formula can be made the basis for roughly determining diffusion coefficients. In the case of mixtures, it is possible to arrive at limits for the concentration, and it has been experimentally proved that hydrogen always appears at the electrode of an acid solution of copper sulphate, in which no currents of liquid are taking place, between the limits of time for the concentration to go down to zero. The time which it takes for the hydrogen to appear can be calculated from an empirical formula, which is similar in form to the one used for a single salt. The great part played by convection-currents in determining the ratio of the two constituents given off at the electrode of an acid copper-sulphate solution, has been shown by proving experimentally that artificial stirring causes hydrogen to disappear altogether in cases where it would otherwise have presented over sixty per cent. of the equivalents carrying the current from the solution to the electrode. The Chairman drew attention to the fact that no hydrogen was liberated until all the copper had gone, and said the formula for the concentration might be used again in further investigations. Dr. Donnan asked if the time at which hydrogen was liberated had been taken as the time at which hydrogen actually made its appearance in the form of bubbles, or whether any allowance had been made for saturation. Dr. Sand said the time was taken up to the appearance of bubbles.—A paper by Dr. R. A. Lehfeldt on electromotive force and osmotic pressure was postponed until the next meeting. The meeting then adjourned until November 9.

PARIS.

Academy of Sciences, October 22.—M. Maurice Lévy in the chair.—On the convergence of meridians, by M. Hatt.—Diagnosis of gaseous supersaturation in cases of a physical order and chemical order, by M. Berthelot. A description is given of attempts made to distinguish between these two classes of phenomena by means of the calorimeter, the reactions studied being the decomposition of dilute solutions of hydrogen peroxide by addition of platinum black or of potassium permanganate. From experiments with the latter reagent, the conclusion is drawn that the considerable quantities of oxygen held in solution are held in the state of an unstable chemical compound.—The origin of atmospheric hydrogen, by M. Armand Gautier. It has been shown in previous papers that air normally contains about ·02 per cent. of free hydrogen. It has been shown that, besides being a normal product of some putrefactive fermentations, hydrogen is given off by many volcanoes, and also escapes from many mineral springs. It is found that certain granites treated *in vacuo* with phosphoric acid give about from three to four times their volume of free hydrogen. Since ammonia is always produced at the same time, the surmise is put forward that nitride of iron, Fe_6N_2, is the source of these two gases. This nitride has not been isolated from these granites, but iron nitrides have been found in the crystalline deposits of the lava fissures of Etna by Silvestri.—Observations on the development of the Onychophoræ, by M. E. L. Bouvier. The species, *Peripatopsis Sedgwicki*, is distinguished from other species of the same genus by the nutritive blastodermic vessicle on the head of its embryos, and by the different stages of the embryo found in the same female,

These facts have already been shortly noticed, but fuller details are given in the present paper.—On the topographical correction of pendulum observations, by M. J. Callet. The method suggested has been worked out for two stations, La Bérarde and Lautaret, situated in the centre of the Alps. The application of the corrections is tedious and lengthy, but the errors of the results obtained are of the same order as those inherent in the pendulum observations themselves under favourable conditions.—Observations of the Perseids, made at Athens, by M. D. Eginitis. The observations were carried out between August 5 and August 12. The meteors were of a reddish-yellow colour, of about the 5th magnitude, and possessed a large number of radiant points.—First results of researches on the recognition of the solar corona at other times than during a total eclipse by means of the calorific rays, by M. H. Deslandres. The possibility of detecting the corona with the aid of a thermo-couple having been proved during the recent total eclipse, daily observations with the same apparatus have since then been carried out at Meudon. The results, although incomplete, show that the presence of the corona can be clearly detected under ordinary conditions in this way. The observations will be continued with more sensitive apparatus.—On the convergence of the coefficients in the development of the perturbation function, by M. A. Féraud.—On the intrinsic equations of motion of a wire, and the calculation of its tension, by M. G. Floquet.—On orthogonal systems admitting a continuous group of transformations of Combescure, by M. D. Th. Egorou.—Index of refraction of bromine, by M. Ch. Rivière. The index of refraction of carefully purified bromine has been determined for temperatures between 10° and 25° for wave-lengths between 790·9 $\mu\mu$ and 592·5 $\mu\mu$, and show that bromine has very great dispersive power, that for rays between A and D at 20° being ·037, compared with ·030 for carbon bisulphide.—The law of moduli. Thermochemical moduli, by M. A. Ponsot.—On the ammoniacal arseniates of cobalt, by M. O. Ducru. The existence of three distinct salts is indicated, which can be distinguished by the pressures at which ammonia commences to be given off.—On a general method of preparation of mixed carbonates of phenols and alcohols, and on the properties of some of these esters, by M. E. Barral. Of the various methods proposed for the preparation of these mixed esters, the best results are obtained by the action of carbonyl chloride upon a solution of the phenol in alcoholic potash or soda, the reagents being all employed in molecular proportions.—Stereochemistry of nitrogen. The stereoisomeric hydrazones of ethyl pyruvate, by M. L. J. Simon. The two isomeric hydrazones are obtained simultaneously, but in unequal quantities. They differ considerably in melting points and solubilities.—Acetals of monovalent alcohols, by M. Marcel Delépine. A thermochemical paper.—On direct nitration in the fatty series, by MM. L. Boauveault and Wahl.—Partial synthesis of laudanosine, by MM. Amé Pictet and B. Athanesesco.—On the pollinisation of cleistogamous flowers, by M. Leclerc du Sablon.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 1.

CHEMICAL SOCIETY, at 8.—Dehydrohomocamphoric Acid and its Oxidation Products: Arthur Lapworth.—Derivatives of Ethyl α-methyl-β-phenylcyanglutarate: W. Carter and W. Trevor Lawrence.—The Nitration of Acetamino-*o*-phenylacetate (diacetyl-*o*-aminophenol)—a Correction: R. Meldola, F.R.S.; and Elkan Wechsler.—Rhamnazin and Rhamnetin: A. G. Perkin and J. R. Allison.—(1) Luteolin, Part III.; (2) Genistein, Part II.: A. G. Perkin and L. H. Horsfall.—Colouring Matter of the Flowers of *Delphinium consolida*: A. G. Perkin and E. J. Wilkinson.—The Action of Alkalis on the Nitro-compounds of the Paraffin Series, Part II.: Wyndham R. Dunstan, F.R.S., and Ernest Goulding.—Hexachlorides of Benzonitrile, Benzamide and Benzoic Acid: F. E. Matthews.—The Influence of Solvents on the Rotation of Optically-active Compounds, Part I.: T. S. Patterson.—Note on Gallinek's Amidomethylnaphthimidazole: R. Meldola, F.R.S., and F. H. Streatfeild.—The Action of Heat on Ethyl-Sulphuric Acid: W. Ramsay and G. Rudorf.—The Amount of Chlorine in Rain-water collected at Cirencester: Edward Kinch.

RÖNTGEN SOCIETY, at 8.—Presidential Address: Dr. J. B. Macintyre.

FRIDAY, NOVEMBER 2.

GEOLOGISTS' ASSOCIATION, at 8.—Conversazione, with Exhibits of Objects and Photographs.

MONDAY, NOVEMBER 5.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Preliminary Examination of Applications for Patents: W. Lloyd Wise.—The Early Manufacture of Sulphuric and Nitric Acids: Oscar Guttmann.

TUESDAY, NOVEMBER 6.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Address by the President, Mr. James Mansergh, and presentation of medals and prizes awarded by the Council.

WEDNESDAY, NOVEMBER 7.

GEOLOGICAL SOCIETY, at 8.—Additional Notes on the Drifts of the Baltic Coast of Germany: Prof. T. G. Bonney, F.R.S., and the Rev. Edwin Hill.—On certain Altered Rocks from near Bastogne, and their Relations to others in the District: Dr. Catherine A. Raisin.

SOCIETY OF PUBLIC ANALYSTS, at 8.—The Determination of the Available Brewing Extract of Malt: Lawrence Briant.—The Definition of the Genuine Product: C. E. Cassal.—Notes on certain B.P. Tests: C. G. Moor and Martin Priest.

ENTOMOLOGICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 8.

MATHEMATICAL SOCIETY, at 5.30.—Annual General Meeting.—On the Transmission of Force through a Solid: Lord Kelvin, G.C.V.O.—In a Simple Group of an Odd Composite Order every System of Conjugate Operators or Sub-groups includes more than Fifty: Dr. G. A. Miller.—Prime Functions on a Riemann Surface: Prof. A. C. Dixon. (i) Further Note on Isoscelians; (ii) On Two In-triangles which are similar to the Pedal Triangle: R. Tucker.—(i) A General Congruence Theorem relating to the Bernoullian Function; (ii) On the Residues of Bernoullian Functions for a Prime Modulus, including as Special Cases the Residues of the Eulerian Numbers and the I-numbers: Dr. Glaisher, F.R.S.—On Green's Function for a Circular Disc: H. S. Carslaw.—On the Real Points of Inflexion of a Curve: A. B. Basset, F.R.S.—On Quantitative Substitutional Analysis: A. Young.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address: Prof. J. Perry, F.R.S.

FRIDAY, NOVEMBER 9.

ROYAL ASTRONOMICAL SOCIETY, at 8.

THURSDAY, NOVEMBER 8, 1900.

SCIENCE AND PSEUDO-SCIENCE.

Genèse de la Matière et de l'Energie—Formation et Fin d'un Monde. Par A. Despaux, Ingénieur des Arts et Manufactures. Pp. 232. (Paris: Félix Alcan, 1900.)

THERE are two classes of writers whose works on scientific subjects possess little or no intrinsic scientific value. The first consists of those who, carrying their distrust of rational authority even beyond the bounds of sanity, run headlong against established modes of thought, and lose themselves in a maze of paradox. To the second class belong authors who, while they show no outward disrespect for the accepted elements of orthodox philosophy, have neither the patience nor the ability to pursue the arduous paths which lead to truth, but with a courage born of want of knowledge of the real difficulties take their own way under the treacherous guidance of blind intuition.

The rapidity of their progress is astonishing, but whether it has an end worth reaching may in general be questioned. The cautious critic finds these excursions difficult to follow, and he therefore has a natural tendency perhaps to do them less than justice. But it may be proper to insist here on the fact that it is of little use even to blunder on a truth unless care be taken to free it from all that is doubtful, and to place it in a convincing light. Failure in this respect constitutes a serious objection to the intuitive method as exemplified by the book under review.

To the representatives of intuitive as opposed to more scientific methods the borderland of the known in science offers great opportunities. In particular, the problems of cosmogony and molecular physics seem to possess a singular fascination for this type of mind. It seems to matter little that these problems present the very greatest difficulties, of which the mere exact formulation is not to be undertaken lightly, and which seem to demand for their solution a mastery over so wide a range of experimental fact and so great a power in the use of mathematical analysis as to have baffled hitherto the most gifted investigators. Indeed, it is being realised more and more how inadequate is the store of facts and how great the need, probably, of an entirely new machinery of analysis. And yet how petty are our discussions, for instance, of the propriety of employing the principle of Action, how futile our doubts about the appropriateness of certain mechanical models to represent ethereal operations! Our intuitive philosophers, as we have said, are ready at one bound to surmount such pedantic obstacles, and why should we not follow them?

The mere title of this book seems to give some justification for suspecting that M. Despaux is not quite innocent of those heretical methods to which we have alluded. Within the modest compass of 232 octavo pages he attempts to explain the origin and nature of matter and energy, the constitution of the molecule, gravitation, many fundamental questions in physics, such as radiant energy and electricity, and, in addition to all this, the formation of the solar system. The scheme is so ambitious that the conclusion seems inevitable that the author has failed to realise the stupendous difficulties to be overcome. And this impression, which is fully confirmed on reading his book, makes it impossible to consider it very seriously. The phenomena to which the author refers are only such as must be well known even to the most elementary student of physics, and if M. Despaux has any claims to be considered a mathematician, his modesty has led him to conceal the fact most scrupulously.

The reader of the book quickly finds that in order to follow the author closely he must gain some idea of M. Despaux' views on the nature of the ether and of the atom. The former he considers as the vehicle necessary for the transference of energy in an undulatory form. Up to a certain point his notions of wave motion are clear and well expressed. Unfortunately, they are as restricted as those of a century ago, and are in effect confined to waves of the condensational-rarefractional type. The result is that the author describes the ether as a discontinuous medium, possessing in some measure the qualities of a gas, thus ignoring all the difficulties which arise from the phenomena of polarisation. On the other hand, his general views on the meaning of action at a distance, and on the ether as the true energy medium, are much more satisfactory and consistent with modern ideas. It is more difficult to follow M. Despaux' suggestions as to the nature of the atom. We gather that there is an essential unity between all kinds of matter, and that all atoms are intrinsically alike. They are the seat of kinetic energy, and appear to be differentiated only by their particular modes of motion. The energy gives rise to vibrations of two types of which one becomes apparent in the form of radiant energy, while the other causes the effect of mutual gravitation and chemical affinity. But lest we should misrepresent his thoughts, we may quote M. Despaux' own words—

"La gravitation est due à la rotation hélicoïdale des atomes ou molécules qui produit une translation dans l'éther; sans rotation, pas de gravité, les corps seraient sans poids, sans chaleur, sans couleur, . . . Ce qui caractérise la matière, c'est en effet le mouvement des atomes bien plus que les atomes eux-mêmes centres de ces mouvements. . . . En résumé, contrairement aux idées reçues, nous estimons que la masse d'un corps dépend moins du nombre des molécules que de leur vitesse de rotation.—Toutes les energies mettant en jeu les attractions et les répulsions sont de même nature que la gravitation" (pp. 94, 95).

Now the implied connection between gravitation and heat is as repugnant to our ideas as the caloric theory of heat itself; for the former involves an identification o mass with energy which is as objectionable as the confusion of a form of energy with matter in the latter. The grounds of objection are, in fact, precisely the same in both cases. The origin of the heresy is to be found in M. Despaux' incapacity to realise the meaning of mass as a distinct entity. He professes carefully to eschew all arguments which appear to him of a metaphysical nature, and yet fails to see that the discussion of fundamental physical conceptions really belongs to the domain of metaphysics. It is distinctly a pity that he has virtually exceeded the limits of his purpose, for his qualifications as a philosopher seem to be inferior even to his equipment as a physicist.

It seems idle to pursue the author further in his speculations. Not content with formulating a theory of the operation of nature on the molecular scale, he devotes the last part of his essay to the exposition of his views on the subject of cosmogony. In this he adopts the nebular theory of Laplace as a general scheme, and applies to it the ideas which he has previously developed. He has an explanation to offer of the cases of retrograde motion in the solar system and of other phenomena which have been thought to present difficulties. On these points he apparently satisfies himself, though others, in the absence of rigorous proof, may remain sceptical. It is in reference to a subject of some debate, the ultimate fate of the solar system, in fact, that he offers a novel suggestion, based on his peculiar conception of the atom. As others have supposed, the end must come with the slow dissipation of energy; but, in the system of M. Despaux, this implies the loss, not only of heat, but also of gravitational power in the atom, or, in other words, of weight. The energy passes to the ether, and matter deprived of its chief property becomes immaterial. The world, then, no longer remains as an inert mass, but reaches its dissolution and leaves "not a rack behind." It is true that M. Despaux contemplates a return of the energy to the atom, and the whole process from the birth to the death of the system repeated in an endless cycle. But even he does not venture to describe in any detail how this is to come about.

Enough has been said as to the scope of this book, and some reason has been assigned for considering it unphilosophical in design and unenlightened in execution. But it is not to be thought that the author is an unfavourable example of the class to which he belongs. He expresses clearly and concisely what he has to say; he is respectful to the great workers who have adhered to the recognised laborious paths; and it should not be thought that there are no ideas to be found in his work which are true, though such as are true may generally appear not to be original. Yet, when all that is said, it is difficult to conceive the utility of such a work.

A NEW TEXT-BOOK ON SOUND.

A Text-Book of Physics. Sound. By J. H. Poynting, Sc.D., F.R.S., and J. J. Thomson, M.A., F.R.S., Hon. Sc.D. (Dublin), Hon. D.L. (Princeton). Pp. x + 163. (London: Chas. Griffin and Co., Ltd., 1899.)

THIS volume will be welcomed by those interested in the teaching of physical science, not only on account of its individual merits, but also as the first instalment of a complete treatise on physics now in preparation by the authors. It is intended for the use of students who lay most stress on the study of the experimental part of physics, and who have not yet reached the stage at which the reading of advanced treatises on special subjects is desirable. For this class of students it is important that the mathematics used should be of the simplest. So far as concerns those who are unacquainted with the calculus, this is self-evident; it is, further, none the less true with regard to those possessing some knowledge of the higher mathematics. Unless great care is exercised, the use of the calculus is apt to become so far mechanical that the student may possibly miss many tacit assumptions which it would be advantageous for him to clearly recognise. To all students it is alike of importance that each stage in the reasoning employed should be brought into view as clearly as possible, and subjected to the most searching scrutiny. This can be done, sometimes by the use of comparatively simple analytical and geometrical devices, often by the application of the principles of the calculus developed *ab initio.* The volume under consideration comprises many most successful attempts to apply simple mathematical methods to the solution of important, and sometimes fairly intricate, problems. The investigation of the modes of vibration of a stretched string, on pp. 86–88, is perhaps the least successful effort in this direction; few students would, it may be feared, be able to keep the essential features of the problem clearly distinguished from the number of geometrical and analytical assumptions and approximations involved. The investigation of the same problem from another standpoint, as given on p. 93, is much to be preferred in this respect.

In the first chapter a good account is given of the general nature and characteristics of sound. A simple experiment, due to Prof. Boys, in which the vibratory character of sound in air is made manifest, might perhaps have been mentioned with advantage. A Bunsen flame is burnt near the end of an open organ pipe, and when the latter is sounded the sinusoidal paths of dust particles traversing the flame are readily seen. From a mathematical point of view, it is to be regretted that a solution is not here given of the problem of the motion of a heavy particle, attracted toward a point with a force proportional to its displacement therefrom. If we suppose the particle to revolve in a circular orbit about the point, then it is easily seen that the centrifugal force must be equal to the central attraction exerted. Resolving the instantaneous displacement, velocity and central force parallel and perpendicularly to any given axis, then we have two harmonic motions executed under the actions of forces proportional to the displacement from the centre. Considering only one of these harmonic motions, the value of the kinetic and potential energies at any point may easily be written down, when it becomes evident that their sum is constant. Equating the potential energy at the extremity of an excursion to the kinetic energy at the point of equilibrium, the well-known expression for the time of vibration is readily obtained. It is interesting to note that this graphical solution corresponds to assigning the real part of $A\epsilon^{iat}$ as the value of x which satisfies the differential equation

$$\frac{d^2x}{dt^2} + a^2t = 0.$$

The second chapter commences with a simple theoretical investigation of the velocity of sound in a fluid, and is followed by an interesting and valuable account of the experimental aspect of the same question. In connection with the reflection of sound, the curious musical ring, often heard to follow each footfall when one is walking near palisading, is simply explained, and Lord Rayleigh's theory of whispering galleries is described. The introduction in ensuing editions of a few reproductions of Prof. Wood's photographs of sound waves would enhance the interest of this section. Refraction of sounds by winds and air-layers of different densities is also

described and explained. The third chapter is occupied with the frequency and pitch of notes, methods of determining the period of a tuning fork, Döppler's principle and musical scales. Whilst comprising little that is new, the account given should prove very useful to students. A short account of resonance and forced vibrations is given in the fourth chapter, whilst the succeeding chapter is occupied with the analysis of vibrations. The mathematical investigation on p. 66, concerning the superposition of harmonic curves, might advantageously have been given rather more in detail considering the class of students for whom the book is written ; but there are few other instances where this objection can be raised.

Chapter vi. is concerned with the vibrations of strings, and a very useful and systematic account of this part of the subject is given. This should prove very acceptable to students as leaving unexplained no point on which difficulties are likely to hang. The vibrations of air in pipes, and of rods, plates and membranes, are treated of in an equally satisfactory manner in Chapters vii. and viii.

One of the most interesting chapters in this volume is the ninth, devoted to singing flames, sensitive flames and jets, and musical sand. Lord Rayleigh's investigation of the conditions necessary for the production of a singing flame is clearly and simply explained, and many other phenomena dependent on similar principles are described. The description and explanation of the musical note, produced when certain sands are struck or otherwise disturbed, will doubtless be read with great interest.

Finally, it may be confidently predicted that this volume will meet with an appreciative reception from all serious students of physics. It is characterised throughout by the absence of obscure and inconclusive reasoning such as is sometimes found in treatises dealing with intricate problems in an elementary manner, by the employment of sound yet simple mathematical methods, and by the inclusion of accounts of recent work not to be found in other books of the same class. Many students might wish that examination questions had been added at the end of each chapter, and some may consider that sixty-six pages of advertisements at the end of the book somewhat exceed what might have been expected in this direction. Otherwise it would be difficult to find grounds for any sentiment but gratification that a gap in our scientific literature has been so worthily filled.

E. E.

GEOLOGY AND PRACTICE.

Steinbruchindustrie und Steinbruchgeologie: technische Geologie nebst praktischen Winken für die Verwertung von Gesteinen, unter eingehender Berücksichtigung der Steinindustrie des Königreiches Sachsen. By Dr. O. Herrmann. Pp. xvi + 428. (Berlin : Borntraeger, 1899.)

IN its elaborate title, of which we have omitted the concluding lines, this work explains its own existence. While it gives a useful account of methods of quarrying, and of the practical applications of various kinds of stone, it specially describes the rocks of Saxony and their economic relations at the present day. The two divisions, general and special, occupy almost equal space, and it will be seen that the book is thus a valuable addition to our libraries. What some of the American States have done for their own areas, what Mr. G. H. Kinahan did for Ireland, in his papers on "Economic Geology," is here repeated for a country of great geological interest. It appears that in Saxony, as in London itself, the use of stone for buildings of a permanent character is becoming more and more extensive, while increasing demands are made upon the quarries for ordinary engineering works.

Dr. Herrmann prefaces his book by an account of the more common rock-forming minerals, and of the rocks ordinarily quarried. This is said to be "zur Orientierung für Nicht-Geologen"; but naturally the elements of mineralogical knowledge are presupposed. A quarry-owner would not be expected to identify his minerals from the descriptions given here, but would doubtless have received, in his preliminary scientific training, a good foundation of chemistry and some practical acquaintance with the materials of the earth's crust. Dr. Herrmann therefore does well to emphasise, in his descriptions, the characters that give each mineral or rock its importance from a technical point of view. The lists of localities, reminding one of those in Roth's "Allgemeine Geologie," and references to the buildings where certain rocks have been employed, might, it seems, have been omitted from this section, in view of the forty-three pages devoted to this subject in a later portion of the work.

The author, writing as recently as 1899 (p. 53), places all the ordinary lavas, rhyolite, basalt, and so forth, as "Eruptivgesteine tertiären und nachtertiären Alters," a classification which is merely playing with words, and which has only a superficial justification in the field. His excuse must lie in the powerful continental combination in favour of an arrangement which, to Western minds, savoured too strongly of the Wernerian school ; its abandonment of late years may, indeed, mark the breaking down of the "mineral cabinet" system of geology, which the spread of microscopic research tended at one time to maintain.

The valuable section of the work (pp. 123–181) on the characters required in rocks selected for various industrial purposes, and on methods of extraction, is illustrated by photographs of actual quarries, taken by the author. We then pass to the special consideration of the application (Verwertung) of the rocks of Saxony to the technical requirements of the country. Many of these rocks are so well known to every student of geology that an account of their mode of occurrence, from a new point of view, is of scientific as well as industrial importance. We notice the tendency to introduce foreign stones side by side with those of some well-worked local quarry, the materials being cut and polished on the same spot. The natural demand for variety in the colour-scheme of our great city-buildings will often limit the demand for a local stone, however excellent, and "foreign competition" may be favoured by good taste as much as by a war of prices.

The account of the Serpentine of Zöblitz, which "has arisen from the alteration of a Lherzolite," is a good example of the interest attaching to the author's mode of treatment. His historical review extends back to the cutting of the stone by a herd-boy, as he watched his cattle, in the middle of the fifteenth century (p. 255).

As an illustration of the many details of geological

value that are probably to be found only in these pages, we may mention the statement (p. 235) that the pitchstones of Meissen are melted up, in increasing quantities, for producing bottle-glass, but that difficulties arise from the very ready formation of bubbles in the mass. This at once reminds us of the experiments of Berger, by which obsidians were converted into pumice before the blowpipe, and of Judd's far-reaching deductions in connection with the lavas of Krakatoa.

An appendix gives, in somewhat unnecessary detail, an account of the road-metal used on the Government roads of Saxony in 1896. The conclusion, however (p. 351), is worth quoting: "Thus, from the group of sandstones, limestones, dolomites, mica-schists, phyllites, slates, loams and clays, which together form 40 per cent. of the surface of Saxony, no material at all was selected for the construction of the roads, while only 1·94 per cent. of the total road-length was made of sands and gravels, which none the less cover great areas." This surprising fact may be commended to our county surveyors, especially in the limestone districts of Ireland. It is true that in France, with a magnificent system of steam-rolling and workmen's caravans, a good road can be made of limestone, if frequently examined and renewed; but the failure in such regions as the Côte d'Or plateaux, where the difficulties of our own Cotteswolds are encountered, shows how much lies in the choice of materials at the outset. Perhaps the eye for minerals, and the natural aptitude for their extraction, which have made Saxon miners the pioneers of Europe, have found expression also in the accurate choice of road-metal.

While Dr. Herrmann's work does not presume to rank as a general text-book, it should be added to our scientific and technical libraries, if only as a record of progress in a State where science is rightly regarded as the inspiring muse of industry. GRENVILLE A. J. COLE.

OUR BOOK SHELF.

Die Mathematik an den Deutschen technischen Hochschulen. Dr. Erwin Papperitz. (Leipzig: Veit, 1899.)
Ueber den Plan eines physikalisch-technischen Instituts an der Universität Göttingen. Felix Klein. (1895.)
Die Anforderungen der Ingenieure und die Ausbildung der mathematischen Lehramtskandidaten. Felix Klein. (1896.)

THESE pamphlets are interesting as showing that the revolutionary ideas brought forward by Prof. Perry on the teaching of mathematics have already begun to agitate the German academic mind; and that his ideas concerning the proper method of presenting the principles of the subject, having regard to the requirements of the student, will receive powerful support in Germany.

The cleavage now going on in mathematical thought was very evident in the recent Physical and Mathematical Congresses, held simultaneously in Paris. The followers of Maxwell and Kelvin found the interest they required in the Physical Congress; the Mathematical Congress was almost entirely engrossed in the development of the analytical ideas of Weirstrass. A lover of music nowadays must become a Wagnerian, or run the risk of hearing no music at all; so, too, the mathematician, who is not absorbed in developments of the convergency of series, must turn to the physical section for the interest he requires.

The Cambridge student of old-fashioned mathematical physics, of the school which the foreigner considered worth imitation, is now driven elsewhere, into the National Science Tripos; and so we find the serious shrinkage in the Mathematical Tripos now in rapid progress. G.

A Glossary of Botanic Terms with their Derivation and Accent. By Benjamin Daydon Jackson. Pp. xi + 327. (London: Duckworth and Co., 1900.)

MR. DAYDON JACKSON has laid those who have to consult botanical literature under a great obligation by the publication of this excellent and compendious glossary. Such a work was badly needed, and no one possesses greater qualifications for the undertaking of it than Mr. Jackson himself, who has done such good work in other departments of an analogous character.

The definitions are usually good and concise, and the errors, so far as we have been able to discover them, are surprisingly few. We cannot help, however, expressing our regret that in the definition of the words "axial" and "axile" the author did not emphasise the difference between them which has been insisted on by some of the best writers. *Axial* should be reserved for structures appertaining to the morphological axis (as distinct from its appendages), *axile* merely denoting position without reference to the morphological nature of the structure concerned. But it would be unfair to tax Mr. Jackson with a confusion only too apparent in literature in which the two terms are frequently used synonymously.

It is often of interest to know by whom a term was introduced, as it is thus possible to ascertain exactly the meaning it was originally intended to convey, and it is to be hoped that Mr. Jackson may see his way to give this information in a future edition. Some of the more recently introduced terms are already dealt with in this way in the volume before us, and we cannot but think that an extension in the direction indicated would still further improve what is already an exceedingly valuable work of reference.

Antropometria. By Dr. R. Livi. Pp. 237. (Milan: Hoepli, 1900.)

THE "Antropometria" of Dr. Livi treats of the subject under three main headings. In Part i. measurements are enumerated and described and their modifying factors reviewed. Instruction is then given in the treatment of data, with especial reference to the statistical method. Part ii. will be found to contain generalisations based on the foregoing sources of evidence, and expressed in the form of laws regulating the rate of growth in various parts of the body; some useful notes on the relation of stature and weight are appended to this part. Part iii. is devoted to an exposition of the principles and method of anthropometric identification, and a stenographic system of recording observations, similar to that used by Dr. Garson in this country, is suggested. Finally, a long table of indices will be found at the end of the volume. Like Dr. Livi's other work, the present contribution to anthropometric literature is thorough and clear; the manual will be extremely useful to students and teachers of physical anthropology.

Elementary Questions in Electricity and Magnetism. Compiled by Magnus Maclean, D.Sc., and E. W. Marchant, D.Sc. Pp. viii + 59. (London: Longmans, Green and Co.)

IT is sometimes a convenience to teachers and students to possess a collection of questions apart from those often given in text-books. There are 311 questions in this volume, arranged under 24 different headings, referring to various sections of frictional electricity, magnetism and current electricity. In addition, the book contains 14 tables of electrical constants, and answers to the numerical questions. The student who works through the exercises in the book will establish his knowledge of electrical principles upon a sound footing.

LETTERS TO THE EDITOR.

Secondary Sexual Characters.

IN his article on "Antelopes and their Recognition Marks" in the number of NATURE dated October 11, Mr. R. I. Pocock suggests that the darker colour of the males in certain species is the outcome or accompaniment of "male katabolism." As generally used, this term seems to denote some peculiarity universally associated with the male sex and giving rise to male peculiarities, so that a character which is the outcome of male katabolism does not require to be explained by the theory of sexual or that of natural selection. This is the sense in which Geddes and Thomson use the term in their "Evolution of Sex": "So brilliancy of colour, exuberance of hair and feathers, activity of scent glands, and even the development of weapons, are not and cannot be explained by sexual selection, but in origin and continued development are outcrops of a male as opposed to a female constitution." But if male katabolism is always associated with the male sex, how is it that there are so many species in which there are no secondary differences between male and female, no outcrops of male katabolism? Either male katabolism, as something different from female katabolism, does *not* exist in the males of all species, or it sometimes exists without producing any visible effect.

It is therefore evident that male katabolism in the kinetic, and not merely the potential, state occurs only in the males of those species which exhibit sexual dimorphism. After all, katabolism is only a name for certain phases of physiological activity, and we thus arrive at the hypothesis that male sexual peculiarities are the result of the peculiar katabolism of the males that possess them. Now we have a reason for such peculiar katabolism, or metabolism, in the special nervous and muscular activity which is observed in the sexual habits of those males which possess secondary sexual characters. This excitement and muscular exertion involves an increase of the metabolism, which goes far to explain, among other things, an increased production of pigment, and the consequent darker or more intense colouring of the males in many instances. The special metabolism is thus due to the habits of life, to external conditions, not to any quality necessarily associated with male sexuality.

It seems to me that, regarding the subject from the point of view I have indicated, we may arrive at the explanation of the darker colour of certain male antelopes, and also of the presence of horns in the males only. If the peculiarities of the male, in particular its colour, are thus the necessary results of physiological processes, they are sufficiently explained, without the additional suggestion that the hornless female has been compelled to adhere to the normal protective colouring of the group, while the males, by reason of their horns and superior strength, have been able to dispense with that advantage. Moreover, Mr. Pocock maintains, in other cases in which horns are developed in the male only, that the markings of the male are protective, for instance, in the kudu. J. T. CUNNINGHAM.

Penzance, October 27.

The Value of the Cylinder Function of the Second Kind for Small Arguments.

IN investigating the propagation of electrical oscillations along cylindrical conductors, the "K_0" function, which satisfies the Bessel's equation and vanishes at infinity, is used to express the vectors outside the wire. Under the conditions of the problem the approximate value of this function for very small arguments is needed. I wish to point out an error in this value, which occurs in all three important memoirs in which the subject has been discussed—viz. those of Prof. J. J. Thomson ("Recent Researches," p. 263), Sommerfeld (*Wied. Ann.*, lxvii. p. 245, 1899) and Mie (*Ann. d. Physik*, ii. p. 211, 1900), an error which can, I think, be traced to a misprint in Heine's "Kugelfunctionen."

The formula given by Heine (vol. i. p. 245) yields as the approximate value $K_0(x) = \log \frac{2}{x} - C + \frac{1}{2}\pi i$.

C is Euler's constant 0·5772 . . . but in the statement of its value which follows $-C$ is printed for C. This mistake, which is not corrected in the errata, is pointed out in the "Treatise" of Gray and Mathews (p. 88, footnote).

If we put $e^{\gamma} = \cdot 5772$, we have $K_0(x) = \log \frac{2i}{\gamma x}$. In the papers referred to, the γ appears in the numerator, which would correspond to the alteration in the sign of C. In Prof. Thomson's work the i in the numerator is omitted.

The error has no effect on the theoretical conclusions reached in the papers. The numerical results given by Sommerfeld and Mie are subject to corrections, which will not, however, affect the order of magnitude. For example, the attenuation constants worked out by Sommerfeld are something like 10 per cent. too small. W. B. MORTON.

Queen's College, Belfast, October 25.

Mosquitoes and Diseases.

AT p. 627 of your issue of October 25, while noticing Profs. Grassi and Noè's observations on *Filaria immitis*, you say "Malaria is not the only disease which is propagated by mosquitoes." May I remind your readers of Dr. Patrick Manson's important observations on *Filaria sanguinis-hominis*, originally communicated to the Linnean Society by Dr. Cobbold, on March 7, 1878 ("On the Development of *Filaria sanguinis-hominis*, and on the Mosquito considered as a Nurse": *Journ. Linn. Soc. Zool.*, xiv., pp. 304–311), and amplified later in a paper communicated on March 6, 1884 ("The Metamorphosis of *Filaria sanguinis-hominis* in the Mosquito": *Trans. Linn. Soc. Zool.*, ser. 2, vol. ii., pp. 367–388, pl. xxxix.)? W. F. KIRBY.

British Museum (Natural History), London, S.W., October 30.

OUR STELLAR SYSTEM.

IN a recently published volume[1] I endeavoured to bring together the facts relating not only to the distribution of stars generally, but to those which the spectroscope has more recently brought before us touching the distribution of the various chemical groups of stars. One of the interesting results of the inquiry was that the Milky Way, which dominates the general distribution, is also the region of the heavens in which undoubted nebulæ giving us bright-line spectra most do congregate. Nor is this all. Those so-called "stars," in the spectra of which bright lines are seen, "bright-line stars" and "new stars," which I have elsewhere shown are nebulæ or stars associated with nebulæ, are also almost entirely confined to the Milky Way. The new spectroscopic knowledge, although so priceless to the student of the chemistry of space, tells us, however, nothing as to the distances of the bodies from us; it only tells us that they lie in the galactic plane. If, however, we combine with the chemical facts the results obtained by Monck, Kapteyn and others touching the proper motions of the various kinds of stars as defined by their spectra, the results we obtain are most definite.

Dealing with the stars generally, it may be stated that the latest inquiries have suggested the following very general classification of stars depending upon temperature:—

Highest Temperature.

Gaseous stars { Proto-hydrogen stars. / Cleveite-gas stars.
Proto-metallic stars.
Metallic stars.
Stars with fluted spectra.

Lowest Temperature.

Now to make the most general statement, we find that the gaseous stars are not only confined to the Milky Way, but they are the most remote in every direction, in every galactic longitude; all of them have the smallest proper motion. The metallic stars are nearest to us, but they are *not* confined to the Milky Way. The proto-metallic stars are intermediate between these two great groups,

[1] "Inorganic Evolution," pp. 124–143.

both in regard to their proper motion and their distribution.

Now the spectroscopic similarity between the gaseous stars and the "bright-line" and "new" stars, and the planetary nebulæ, justifies our assuming provisionally that they exist under some similar conditions, and, as they are all confined to the Milky Way, we are further justified in assuming that they lie at the same distance from us.

The smaller proper motion of the hottest stars, in which I include the bright-line stars, proves that the region which gives rise to them as well as the new stars, and the planetary nebulæ, is far away *on all sides*. If it were not so we should get a very small proper motion in one direction and a very large proper motion in another.

But the stars in question in the Milky Way, which is a great circle, are all equally remote; and the only place whence such a state of things can be observed must be a point equally distant from all, that is, in the centre of the system under observation.

It is worth while to repeat that it is because we are in the centre, because the solar system is in the centre, that the observed effect arises, and if we imagine the solar system very far from the centre we should get very different proper motion conditions on this side and on that; but seeing that we have found that we get the smallest proper motion with regard to all the hottest phenomena that we know of in space, we have to consider that the still truly nebulous region is far away from us in every direction, and that it practically is limited to the plane of the Milky Way.

Photographs of some drawings made by Herschel, when he was first brought into the presence of the wonderful nebulæ with which the heavens are peopled, will give an idea of what possibly may be the condition of things touching our own system. We have amongst them drawings of "globular" nebulæ, possibly not globes, but systems looked down upon from their poles, and the possibility of that arises from the fact that many nebulæ are looked at edge-ways, and are very thin. Hence we do not know that the apparently globular clusters are not really those things looked at from the poles of their movement. We have not only those globular and elliptic nebulæ, but we have double elliptic nebulæ, which might be considered as explaining how the Milky Way happens somehow or another to be doubled. In addition to these we have well-defined ring nebulæ, the best example of which is in the constellation Lyra. It has been often imagined, up to now, by those who have considered this subject, that the Milky Way owes its appearance to the fact that there is really a spiral nebula in question, and that the stars which form the stellar system and form the companions of the sun exist at the centre of a spiral nebula. One of these spiral nebulæ, which we observe looking down on the whole system from the pole is the spiral nebula in Canes Venatici. The wonderful nebula in Andromeda, also a spiral nebula, we look at side-ways, and so it appears elliptical, and in this we notice that the greatest condensation is in the centre. But we know, from what I have stated, that our greatest condensation is not in the centre; in our case the greatest vacuity is in the centre. We are in the quiet, in the centre; so that certainly if we take our choice of these different forms, we must say that our system is much more like that of the ring nebula in Lyra than it is to such systems as those in Canes Venatici and Andromeda. We, according to Gould's work, have in the centre of our system, represented by the Milky Way, a small number of cooling stars all congregating together; outside that at an infinite distance from these relatively cool bodies, we have the Milky Way stretching with all its concomitants of gaseous stars, planetary nebulæ, bright-line stars, new stars, and so on. We must therefore consider that in our present knowledge such a condition of things as is represented by the ring nebula in Lyra fits our facts very much better than the condition which is represented by such a spiral structure as Andromeda, in which the greatest heat—I say that because there is obviously the greatest luminosity—is located at the centre. I have already referred to the proper motion evidence. It is obvious that in the case of the nebula of Andromeda, if we imagine an observer at the centre, large, medium, and small proper motions would be observed in every direction in the plane of the system, for the reason that the spirals lie in some cases near to, and in others far from, the centre, and that there are many spirals. We practically know that in our system the centre is the region of least disturbance, and therefore cooler conditions.

I now come to another point which must be considered in the next place.

Let us assume for the moment that the average brightness of stars depends upon their distance; then the

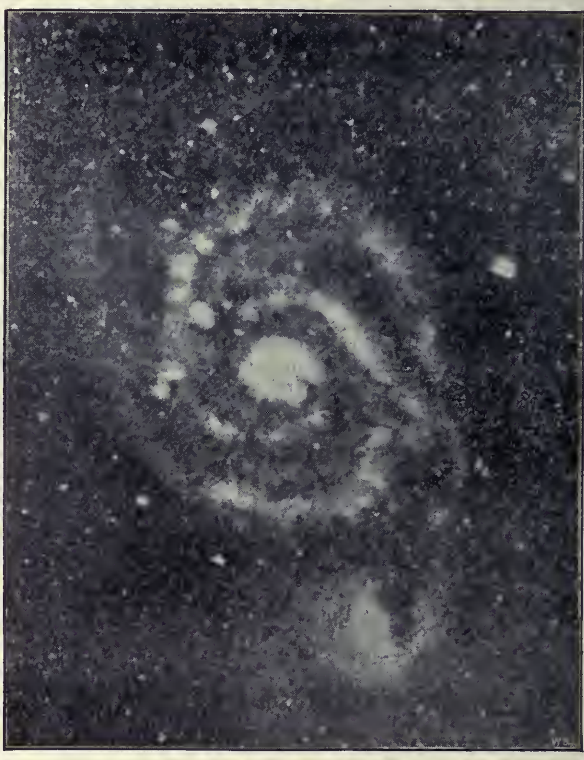

FIG. 1.—Spiral nebula of Canes Venatici, from a photograph by Dr. Roberts.

number of stars of a given magnitude indicates the stellar density at a corresponding distance. Gould from actual enumeration has given a formula which shows us that if the stars were uniformly scattered in space, and the light from them suffered no extinction in coming to us—if it did not meet anything that it could not get through—then the number of stars visible to us through a telescope, such as we have at Kensington or at Mount Hamilton, should be about 12,000,000,000. But the number actually visible, so far as counts are concerned, is certainly very much less, and, in fact, it has been estimated that the countable number, instead of being 12,000,000,000, is only about 100,000,000. This estimate seems to me very low, but I am bound to give it. When we come to consider the stars of different magnitudes in different parts of

space, we find a very great difference in relation to the plane of the Milky Way; but irrespective of this it may be said that omitting some 500 of the brighter stars, which have to be classed separately, up to the 9th magnitude, the actual and theoretical numbers are fairly accordant, but there is a distinct indication of a thinning out of stars after the 9th magnitude is passed. An example of this has been furnished by Prof. Pickering, who has given us a very useful diagram of the brightness of the stars seen within 1° from the celestial pole: that is to say, a region about 28° from the Milky Way. There is a very considerable number of stars of the 9th and 10th magnitudes, but very few of the 14th and 15th. In

Fig. 2.—The great nebula in Andromeda, from a photograph by Dr. Roberts.

that way it is possible to investigate the conditioning of stars with regard to their brilliancy in the Milky Way itself; the value of the diagram now given is that it shows what happens in a position away from the plane.

There is one other point which arises which is well worth our attention. It is a subject that we have to approach with caution, because it is such a large one, and because so little is known about it. When we look away from the plane of the Milky Way to the poles, we find, as the late Mr. Waters very conclusively proved to us by his tabulations, the greatest number of so-called nebulæ; it is very difficult to discuss this matter, because the nature of these nebulæ is undefined, we are without any information as to whether they are gaseous nebulæ or non-gaseous, and we may burn our fingers by talking about them. If, however, we consider the matter from the point of view at which we have now arrived from the complete discussion which is open to us, the question arises whether this enormous increase of nebulæ towards the poles of the Milky Way

Fig. 3.—The ring nebulæ in Lyra.

does not show us that these things are probably other universes, other systems, like our own. We must consider most of the stars which we see with our most powerful telescopes as belonging to our own system. The number, as we know, increases tremendously as the plane of the Milky Way is approached, and it is possible that as that central plane of the system contains not only stars but nebulæ, it must also contain any number of dark bodies down to the smallest meteorite, and that we may possibly have there a *vera causa* for an extinction of light near the plane of the Milky Way, which is not possible in other parts of the heavens, especially towards the galactic poles. If that be so, the increase of "nebulæ" towards the poles of the Milky Way may simply mean that we see other universes than our own in greater plenty where the conditions for seeing them become more favourable, and that is the reason why towards the poles of the Milky Way we have this overpowering number of apparently nebulous bodies. Of course if that be so, what will turn out will be that most, if not all, of them are not nebulæ at all; they are systems like our own, are clusters of stars with which our own system has absolutely no concern or connection.

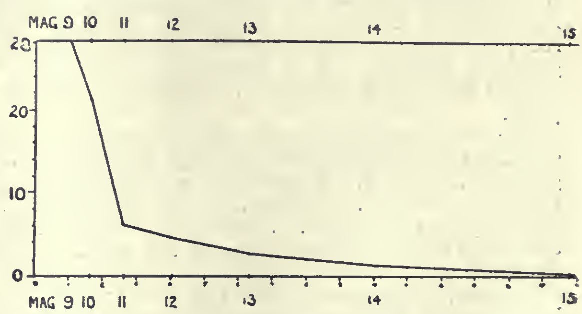

Fig. 4.—Pickering's diagram.

It follows also that the overwhelming number of very faint stars in the Milky Way are stars which would appear brighter if they happened to lie near the galactic poles.

The above suggestion is only an extension of an idea first put forward I believe by Schiaparelli. In spite of the considerable literature on the subject of the extinction

of light in space, it was not till 1889, so far as I can make out, that the possibility of such an extinction being brought about by fine particles of matter was suggested,[1] and he referred to the constitution of comets, falling stars and meteorites in support of this idea.

Now that the nebulæ and stars giving us bright-line spectra, as well as comets and falling stars, have been associated with meteorites, we must expect that the extinction of light, if produced as suggested by Schiaparelli, must very rapidly increase as the Milky Way is approached.

Hence the small magnitude stars in the Milky Way are stars of which the light has been dimmed, and the gap which separates system from system may be gathered from Pickering's diagram (Fig. 4).

We may perhaps, after the recent surveys of space, go a little further than Schiaparelli. A stoppage of light by solid bodies, whether small meteorites or condensed stars like the sun, would affect the spectrum equally from one end to the other. But we now know that many of the stars are not condensed bodies like the sun, and that in the surroundings of these, as well as in the so-called gaseous nebulæ, are gases and vapours which would undoubtedly stop the short more than the long waves of light passing through them; and there is ample evidence, as we have seen, that such stars and nebulæ are more numerous in the plane of the Milky Way than elsewhere. If we take stars of the same chemical species in and away from the Milky Way, and find differences in the lengths of their spectra in the ultra-violet, the inquiry would be carried one stage further.

It is a sure sign of the interest taken in such subjects as these, that, since the above was written, two important contributions to our knowledge have appeared. I hope it may be possible for me to refer to them on a future occasion.

NORMAN LOCKYER.

[1] "Sulla distribuzione apparente delle Stelle viribili ad occhio nudo."

THE MALARIA CAMPAIGN.

DURING the last two years, no subject has been more discussed in the medical world than paludism, and in the discussion the general public has taken an interest which purely medical matters seldom enjoy. But this is not a matter of only scientific interest, as is readily seen when one hears that five million human lives are the toll India alone pays annually to the grim spectre of malaria.

The prevention of malaria is a problem of great human, political and economic importance, and the Secretary of State for the Colonies, and many wealthy individuals in London and Liverpool, have shown their recognition of this fact by great personal interest and generous contributions of money for the founding of schools of tropical medicine in these two great seaports.

The fact of mosquito agency in the spread of malaria suspected by many, asserted by King (now almost forgotten), Laveran and Manson, and subsequently proved by the brilliant work of Ross, was not accepted at all generally two years ago. Since then, however, expeditions have been to various parts of the world to study the whole question anew.

Two expeditions have been sent to our colonies in West Africa by the Liverpool School of Tropical Medicine, another by the Royal Society to British Central Africa, some members of which subsequently followed the Liverpool men to West Africa, and lastly, in May of this year, at the instance of Dr. Patrick Manson, the London School of Tropical Medicine despatched an expedition, of which more anon, to the Roman Campagna.

In addition to these special expeditions sent out from home, Bignami, Celli, Grassi and other well-known Italian observers have been hard at work in their own country, while many medical men of our Colonial service have in their own districts been on the trail of the malaria parasites.

Germany, too, as is her wont, has been equally energetic. The great Koch, at the head of several expeditions, has visited many parts of the world and contributed largely to the sum of our present knowledge. Furthermore, Hamburg, the principal German seaport, has rightly been chosen the seat of a school of tropical medicine, whose objects are identical with those of our own schools and whose head is Prof. Nocht. It is interesting to note that the foundation of this school is due to the initiative of the Imperial Government and the enterprise of the municipal authorities of Hamburg. Save sympathy, our English schools owe nothing to the Government of an empire whose interests are more vitally affected by the problems of tropical medicine than any other in the world.

In the aggregate, the addition to our knowledge from these various sources has been immense. The whole life-history of the Hæmamœbidæ responsible for malaria has been accurately worked out, and a particular genus of mosquito (Anopheles) has been, after due trial, definitely convicted of carrying these parasites from man to man and of acting as definitive host to the parasite during its sexual phase of development. On the other hand, man, the intermediate host in this cycle of alternation of generations, has been proved equally necessary for the propagation of the species. A constant association therefore of man with mosquito seems the rule in a vicious circle, which keeps up the supply of parasites and precludes the possibility of their destruction and extinction.

One day, however, it may be shown that the human Hæmamœbidæ can complete their asexual cycle in some mammal other than man. But as yet there is no evidence of this, and Koch has stated his disbelief in the existence of any second alternative host.

As soon as there was a fair presumption (if not positive proof) that the parasites of malaria multiplied by a process of alternation of generation, in which man and a mosquito played the leading parts as intermediate and definitive hosts respectively, all workers in the subject turned their attention to the identity of the species of mosquito concerned, their habits and bionomics, and to the best method of applying practically their newly-found knowledge with a view to reducing the ravages of the fever.

New species of Anopheles were met with, and statistics of health and meteorological observations collected, with the result that our knowledge of mosquito life generally, and especially its relation to malaria, has greatly increased. Major Giles, in his recent monograph on "Mosquitoes," has collected and arranged many of the new facts, but even now we do not know how many varieties of Anopheles there are nor are we certain if all species of this genus are hospitable to the malaria parasites.

In a report recently issued by the trustees of the British Museum, Mr. F. V. Theobald gives us much further information about the Culicidæ, their distribution in nature and some points to help in the identification of species. From this report we learn that twenty-two species of Anopheles are now known, and of these ten are entirely new to science, while of Culex some ninety new species have been described.

It would appear that as a genus Anopheles is worldwide in its distribution, but is more limited in regard to species. This pamphlet is a valuable contribution to knowledge, and is evidence of the magnitude of the work now being done to increase our meagre knowledge of the Culicidæ and gives a good idea of the special difficulties of the subject.

Necessarily there has been some differences of opinion, and what has been found true in one place has been denied elsewhere. This is not remarkable if one considers how much mosquito life and habits are influenced by meteorological factors, and these obviously differ greatly in different latitudes and at different altitudes. On certain essential points, however, all observers are agreed: malaria is caused by three (possibly four) species of the Hæmamœbidæ, and these are indisputably conveyed from man to man by mosquitoes of genus Anopheles.

Another important point has been noted in West Africa by Stephens and Christophers and by Koch in Java and elsewhere. Native children of one to three years old are peculiarly the victims of malaria parasites, and as they grow older the invasion by parasites becomes less and less. These facts have been taken to prove what has long been asserted, viz., that prolonged residence in a malarial country produces a relative amount of immunity.

Koch used the presence or absence of parasites in the blood of young children as a criterion of the question as to whether malaria was endemic or merely imported. It further shows how great a danger to white men is living in close proximity to native habitations. This has been insisted on in West Africa, much to the indignation of the educated blacks.

Incidentally, additions to our knowledge of the fauna of West Africa have been made by these expeditions. Mr. Ernest Austen, of the Zoological Department, British Museum, accompanied the first expedition to Sierra Leone, and a report on his work there has been recently published by the authorities of the museum.

Fifteen hundred specimens of insects were obtained, chiefly of the Lepidoptera, Diptera and Neuroptera, though four other orders were represented in the collection. In his report Mr. Austen describes a variety of Tsetse fly (*Glossina longipalpis*), and a Muscid (probably new) known locally as the "Tumba" fly. The latter deposits its egg under the skin of man and other animals, and when the larva is hatched a boil of a peculiarly painful character is produced. The departure of Mr. Austen, immediately on his return from Sierra Leone, to South Africa with the City Imperial Volunteers has prevented us as yet of obtaining the full fruits of his work, which, now that he has safely returned, we shall eagerly look for.

The best methods of malaria prophylaxis have been much discussed. The original views of Major Ross and the first Liverpool expedition, in the light of wider and more recent knowledge, seem somewhat too sanguine. The destruction and extermination of mosquitoes by drainage and the use of culicicides, as suggested in their report, is now regarded as impracticable in some districts, although in many places these methods, in conjunction with the intelligent use of mosquito-curtains and quinine, could not fail to bring about a marked improvement.

On the whole, however, we must rely, as Dr. Manson has insisted, on the prolonged treatment of patients with quinine and during the time they have parasites in their blood on their rigorous isolation and protection from mosquitoes.

Paradoxical as it may seem, we must first aim at preserving mosquitoes from infection and so limit the chances of the dissemination of the parasites as far as possible.

It cannot be too strongly emphasised that in a malarious country where Anopheles are present a case of fever is infectious.

The value of the proper use of mosquito netting is strikingly shown by the following experiments. In March last Dr. Manson, speaking at the Colonial Institute, announced that the Colonial Office, in conjunction with the London School of Tropical Medicine, had authorised him to make an experiment to show the practicability of preventing malaria by easily applied means. A hut was to be erected in the most malarious part of the Roman Campagna with wire gauze doors and windows so as to render it mosquito proof. This hut two skilled observers were to occupy from May to October, that is, during the whole malarial season. By day they would be able to go out, but at sunset, before the mosquitoes rose, they were to enter their hut and remain closed in until daybreak. By this means it was contended they would be free from all possibility of infection by mosquitoes. In accordance with this plan Drs. Low and Sambon, of London, took up their residence in June, and the latest information is that they have passed through a trying ordeal unscathed and without any appearance of fever. This experiment is of great value, though open to criticism on the grounds that the conditions are somewhat artificial.

A similar experiment, under more natural conditions, and therefore, perhaps, of a more searching character, has been tried by the members of the second Liverpool expedition to West Africa. For four months, in the most malarious districts on the Niger, Drs. Annett, Dutton and Elliott have lived, relying, not on quinine, but only on their proper use of mosquito curtains. A recent communication shows that they have retained their health throughout their stay.

Another important experiment has recently been tried, an experiment which may be considered the complement of those just mentioned.

A consignment of Anopheles, fed on the blood of a patient in Rome known to contain parasites, was received in London from Prof. Bastianelli in July last. A son of Dr. Manson, who had not been in a malarious country since childhood, submitted himself to the bites of these infected mosquitoes. Within a fortnight Mr. Manson had a typical attack of fever, and in his blood were found parasites similar to those causing the fever of the Roman patient on whom the mosquitoes had originally been fed.

This is a crucial experiment, and proves to the hilt, if further proof were needed, that malaria is conveyed by mosquitoes from man to man. Similar "feeding" experiments had been done before, but never has such a striking and satisfactory demonstration been obtained. We have now to deal no longer with theories, but with facts, and it remains to put into practice the valuable information we have obtained as to the possibility of limiting malaria, and so improve the sanitary condition, and thereby increase the commercial prosperity of many of our greatest colonies.

R. FIELDING-OULD.

THE GEOLOGICAL SURVEY OF GREAT BRITAIN AND IRELAND.[1]

THE summary of progress of the Geological Survey of the United Kingdom for the year 1899 has been issued by Sir Archibald Geikie, Director-General. The field-work was carried out in England and Wales principally in the coal districts and bordering tracts of North Staffordshire, Leicestershire and Glamorganshire; in the slate and granite areas of Cornwall; and in the Cretaceous and Tertiary regions of the southern and southern-midland counties. In Scotland the survey of the Highland regions was prosecuted as vigorously as the nature of the ground permitted, and progress was also made in the surveys of Arran and Skye. In Ireland the revision of Silurian areas was continued.

The bulk of the summary is taken up with a somewhat detailed record of the observations made in the field; and

[1] "Summary of Progress of the Geological Survey of the United Kingdom for 1899." Pp. v + 214. (London: Printed for H.M. Stationery Office, 1900.)

this is supplemented by an account of work done in the petrographical and palæontological departments of the Survey. The field record is arranged stratigraphically, beginning with the pre-Cambrian rocks and ending with the recent deposits. Thus there are notes on nearly all the main geological systems, excepting only the Cambrian, Permian, and some of the Tertiary divisions.

In the accounts of Highland regions we find many references to the complex folds, the faults and thrust planes, which have affected the Lewisian gneiss, the schists of the "Moine series," the Torridonian and other rocks. In some cases highly altered rocks are found to overlie others which are less altered, showing that the metamorphism must have taken place before the rocks occupied their present relative positions. In places the Moine rocks contain intrusions of partially foliated hornblendic rocks, and some of these are foliated parallel to their sides and cut both the banding and the foliation of the rocks in which they occur.

It seems probable that the Moine schists of the north-west pass into and form part of the Dalradian series of the central Highlands. It is also considered probable that the Moine schists acquired their present crystalline characters since Cambrian times. Moreover, from the fact that the phyllites, quartzites, grits, conglomerates and limestones which extend from the shores of Elgin, Banff and Aberdeen to those of Islay and Jura have had a sedimentary origin, it is thought that they may yet find a definite place among pre-Cambrian or even post-Cambrian formations. In connection with this subject it is to be remembered that a belt of rocks, possibly of Arenig age, has been traced at intervals from Kincardineshire to Dumbartonshire. Here the rocks are wedged in along a line of disturbance between the Highland schists and the Old Red Sandstone; and they comprise graphitic shales, schists and cherts with Radiolaria. Rocks of this character have now been discovered in Arran.

Another interesting discovery is chronicled in the account of the work among the Silurian rocks of Ireland. The majority of the igneous rocks of the Waterford coast have been regarded as volcanic sheets intercalated contemporaneously among the Lower Silurian sediments. Evidence is now brought forward to show that these rocks, which were believed to be tuffs and agglomerates, are intrusive, the "agglomerates" having been in reality produced by a process of brecciation during a prolonged period of igneous intrusion.

It has been pointed out in a previous issue of the "Summary of Progress," that the detailed study of the rocks in the North Staffordshire Coal-field has shown that the coal-measures extend over a much wider area at or near the surface than was previously thought. Evidence furnished by a bore-hole at Thurgarton near Nottingham confirms the persistence and importance of the subdivisions that have been recognised and mapped in the North Staffordshire coalfield.

Much new information has also been gathered in the great Coal-field of South Wales, and some remarkable disturbances accompanied by over-thrusting are figured. Interesting also are the observations which have been made on the secondary rocks in this coal-basin. The occurrence of a red and green marl in the upper part of the Rhætic group at Coity, near Bridgend, and onwards to near the famous old Pyle Inn, is significant as showing the local continuation of conditions akin to those of the Keuper Marl in the Rhætic period.

Fossils of Rhætic character have been found in the passage-beds between the Red conglomerates and Lower Lias of Skye. More important still is the discovery of Rhætic fossils in the island of Arran. Here the beds which have yielded the specimens are not actually *in situ*, but are enclosed in a coarse conglomerate that fills a volcanic vent, probably of Tertiary age.

In the accounts of Lower Cretaceous rocks mention is made of fossils obtained from the Sandgate Beds, near Midhurst; and in the records of Tertiary strata there are notices of new fossiliferous localities in the Reading Beds, London Clay, Bagshot Sands, Bracklesham Beds and Barton Clay of Hampshire.

Among the Tertiary igneous rocks of Skye much new information has been obtained. The gabbro is described as consisting of numerous distinct intrusions in the form of wedges, sheets and tongues. In the basalt plateaux west of the Cuillin Hills the salient features of the slopes are due to the numerous hard intrusive sills intercalated among the softer lava flows. These latter are in general amygdaloidal. References are made to other and later sills which differ from those which follow the bedding-planes of the lavas.

Glacial drifts have received much attention in various parts of the country. Perhaps the most interesting result obtained is that having reference to the sequence in the Gower promontory of South Wales. Evidence is given to show that the deposits holding the Pleistocene fauna in the caves are newer than the raised beach, and that these bone-beds are overlain by the glacial drift.

Of special petrographical work the descriptions of the volcanic rocks of the Exeter district are noteworthy. The results of a further examination of olivine-monzonites from Argyllshire are also stated. Analysis is given of a manganese deposit of Culm-measure age at Hockworthy in Devonshire.

Of palæontological work mention should be made of the detection of phosphatic nodules with traces of probable cell-structure in the Torridonian rocks of Ross-shire. A useful catalogue is also appended of the Eocene and Oligocene type fossils which are preserved in the Museum of Practical Geology.

NOTES.

THE following Fellows of the Royal Society have been recommended by the president and council of the Society for election into the council for the year 1900, at the anniversary meeting on November 30. The names of the new members of the council are in italics. President: *Sir William Huggins, K.C.B.* Treasurer: Mr. A. B. Kempe. Secretaries: Sir Michael Foster, K.C.B., Prof. A. W. Rücker. Foreign Secretary: Dr. T. E. Thorpe, C.B. Other members of the council: *Prof. H. E. Armstrong*, *Mr. C. V. Boys*, Dr. Horace T. Brown, Mr. W. H. M. Christie, C.B., Prof. E. B. Elliott, Dr. Hans F. Gadow, *Prof. W. M. Hicks*, Lord Lister, *Prof. W. C. McIntosh*, *Dr. Ludwig Mond*, Prof. A. W. Reinold, *Prof. J. Emerson Reynolds*, *Dr. R. H. Scott*, *Prof. C. S. Sherrington*, Mr. J. J. H. Teall, *Sir J. Wolfe Barry, K.C.B.*

THE Royal Society's Medals have this year been adjudicated by the president and council as follows:—the Copley Medal to Prof. Marcellin Berthelot, For. Mem. R.S., for his brilliant services to chemical science; the Rumford Medal to Prof. Antoine Henri Becquerel, for his discoveries in radiation proceeding from uranium; a Royal Medal to Major Percy Alexander MacMahon, F.R.S., for the number and range of his contributions to mathematical science; a Royal Medal to Prof. Alfred Newton, F.R.S., for his eminent contributions to the science of ornithology and the geographical distribution of animals; the Davy Medal to Prof. Guglielmo Koerner, for his brilliant investigations on the position theory of the aromatic compounds; and the Darwin Medal to Prof. Ernst Haeckel, for his long continued and highly important work in zoology, all of which has been inspired by the spirit of Darwinism. Her Majesty the Queen has been graciously pleased to approve of the award of the Royal Medals. The medals will, as usual, be

presented at the anniversary meeting on St. Andrew's Day (November 30). The Society will dine together at the Whitehall Rooms on the evening of the same day.

To commemorate Huxley's anthropological work, the Council of the Anthropological Institute of Great Britain and Ireland has decided to found a public lecture, which will be called the "Huxley Memorial Lecture," and will be given annually at the opening of the winter session of the institute. The first Huxley lecture will be delivered by the Right Hon. Lord Avebury, F.R.S., and is announced for Tuesday, November 13, at 8.30 p.m., in the lecture theatre of the Museum of Practical Geology, Jermyn Street, S.W., which, as the scene of so much of Huxley's most impressive teaching, was felt to be the most appropriate place for such a ceremony, and has been placed for the occasion at the disposal of the Anthropological Institute. Applications for tickets of admission should be addressed to the Secretary, the Anthropological Institute, 3, Hanover Square, W., as early as possible.

Many aspects of the subject of water supply were considered by Mr. James Mansergh in his presidential address to the Institution of Civil Engineers on Tuesday. First and foremost is the question of rainfall and its accurate registration, as providing the prime factor in ascertaining the capability of supply of any given drainage area, with the flow off watersheds of varying form and geological structure, the losses by evaporation, and the discharge by floods. From the point of view of the waterworks engineer, this information is of the highest importance, and has been dealt with by previous presidents of the Institution. On the question of purity, which means, according to the now generally accepted opinion, the absence from the water—as delivered to its consumers—of any pathogenic organisms, the responsibilities of the water engineer are daily becoming more exacting. The best methods of examining and purifying waters for drinking purposes are scientific problems which have not yet been completely answered; and Mr. Mansergh showed in his address that water engineers are awaiting the expression of a definite opinion as to what organisms are actually harmful and what means should be used to remove them.

A private conference was held at the Board of Trade last week to consider the protection of the delicate instruments in use at Kew and Greenwich Observatories from magnetic disturbance, through the working of tramways and railways in the metropolis by electricity. Sir Courtenay Boyle presided, and among the officials of the Board of Trade present were Mr. F. J. S. Hopwood, Sir Thomas Blomfield and Mr. Trotter. The observatories and kindred public departments were represented by Mr. Christie (the Astronomer-Royal), Prof. Rücker, Mr. Glazebrook (Director of the National Physical Laboratory), Lieut.-Colonel Raban (Director of Works at the Admiralty), Admiral Sir W. J. Wharton (Hydrographer to the Admiralty), and Profs. Ayrton and Perry. Among those who attended as representatives of the railway and tramway interests concerned were Mr. George White (chairman) and Mr. J. Clifton Robinson (engineer) of the London United Tramways Company, Sir Benjamin Baker and Sir W. Preece. The conference is mentioned in Prof. Perry's address, on p. 46 of the present issue.

A method of diminishing the disturbing effects of electric tramways on magnetic observatories forms the subject of a note by M. Th. Moureaux in a recent number of the *Comptes rendus*. The observatory of Parc Saint Maur is at a distance of about 3·2 kilometres from a line of electric trams between Vincennes and Nogent sur Marne, and the disturbances are due chiefly to erratic currents, which exhibit their influence, not in the form of permanent displacements, but in series of vibrations, symmetrical with respect to the axis of the curves. The effect attains a maximum corresponding apparently to the starting of the cars after stoppages. M. Moureaux recommends as a remedy (1) the use of powerfully magnetised bars of rectangular or square section, (2) the addition of masses of copper with the object of increasing the moment of inertia of the oscillating system, (3) the use of a damper. The author has introduced these modifications into a declinometer and a bifilar magnet, and observations have been made with the new instruments, not only at Parc Saint Maur but also at the forts of Vincennes and Nogent, which are situated in much closer proximity to the tram-line. The general result was a decrease of the disturbing effects of the electric currents to about one-tenth of their former value. It was found that the efficiency of the instruments in recording natural disturbances was in no way impaired by the modifications in question, the records of a small disturbance made with two of the new bifilar instruments at Nogent coinciding in every detail with those taken at Parc Saint Maur.

In recognition of the services rendered to chemical science by Prof. A. W. Hofmann, new premises have been erected in Berlin for the occupation of the German Chemical Society, and the building has been named "Hofmann Haus." We learn from the *Pharmaceutical Journal* that the formal opening of the building took place on October 20, in the presence of a large number of Government officials and many representatives of the universities and other scientific institutions of Germany. The first step towards the establishment of this memorial was taken in 1888 at the celebration of Hofmann's seventieth birthday, when a sum of 300,000 marks was subscribed for the foundation of an Institute that, besides providing a laboratory for chemical investigation, would serve as a home for scientific societies and a place for meetings, lectures or exhibitions, &c. After Hofmann's death in 1892 the scheme was warmly taken up; the Empress Frederick, who had been a pupil of Hofmann's, supported it by accepting the position of patroness, and with the aid of Dr. J. F. Holtz it has now been successfully carried out, so that the Hofmann Haus could be handed over to Prof. Volhard, the president of the German Chemical Society. The same evening the first meeting was held in the new premises, when addresses were delivered by Prof. v. Baeyer of Munich, and Dr. Brunck, the Director of the Badischen Aniline and Soda Factory, describing the synthesis of indigotin and the development of its manufacture at Ludwigshafen.

At a meeting of the Council and Members of the Victoria Institute held on Monday, November 5, the president, Sir George G. Stokes, F.R.S., in the chair, Prof. Edward Hull, F.R.S., was elected secretary of the Institute in succession to the late Captain Francis Petrie.

The annual course of Christmas lectures, specially adapted to young people, at the Royal Institution, will be delivered by Sir Robert S. Ball, F.R.S., whose subject is "Great Chapters in the Book of Nature." The first lecture will take place on Thursday, December 27, at three o'clock.

A Reuter message from Simla states that since the Pasteur Institute was opened at Kasauli under the direction of Major Semple, seventy-five patients have sought admission, sixty-two of whom completed the course. In no case has the treatment ended in failure, though several of the patients had been bitten on the face by dogs and jackals. Seven British officers, twenty-five soldiers, and twelve European civilians have been treated. The rest of the patients were natives. It is evident that the institute continues to supply a pressing need.

Overhead wires conveying electric currents for tramway traction are certainly unsightly, and an accident which a *Time* correspondent reports from Vienna reminds us of their danger.

A telephone wire which had broken fell upon the overhead wire of the new electric tramway line and made connection with the earth. A lady, who got caught by the loose wire, and three men who went to her assistance, were injured by the current. Two of the persons were so seriously injured that they had to be taken to a hospital, and one is not expected to recover. From the report it is not quite clear how the woman got entangled with the telephone wire, and if the wire coiled round her in falling she might, of course, have been seriously injured, even if no current from the overhead wires of the tramway line had been passing through it. There is danger when a wire breaks, whether the wire comes in contact with one conveying a strong electric current or not. The accident might, however, have been prevented had nets been placed, as is sometimes cautiously employed, over the tramway overhead wires at places where telephone or telegraph wires cross them.

AT the Imperial Institute, on Monday, Mr. James Stirling discoursed upon "Golden Victoria, its Scenery, Geological Features, and Mines," and gave a glowing account of its resources. Victoria, although the smallest State in the Australian Continent, is the most varied with regard to its surface features, natural resources, climate, &c. It has produced, during the last half-century, more gold than any other country in the world, California excepted, viz., 256 millions out of the total 413 millions produced by Australasia. Bendigo, the deepest mine, is now 3434 feet in depth. Boring operations have proved that deep auriferous leads of about 400 miles in extent exist in various parts of the Colony. The coalfields cover, in Gippsland alone, 3000 square miles of territory, and the seams are up to 5 feet in thickness. In several valleys, such as the Latrobe, immense deposits of brown coal 276 feet thick have been found.

THE *Times* states that the practicability of utilising Mr. Marconi's system of wireless telegraphy in connection with the mail packets running between Dover and Ostend has just been tested, with satisfactory results. The vessel selected for the demonstrations was the Belgian mail packet, *Princess Clementine*, commanded by Captain Romyn. The installation was fitted up in one of the private deck cabins on the starboard side. The receiving and sending wires were connected to the foremast, the height of which had been considerably increased. The land installation was set up at La Panne, on the flat coast between Ostend and Dunkirk, the mast being about 130 ft. in height. The distance between La Panne and Dover is 61 miles. The *Princess Clementine* left Ostend soon after 11 o'clock on Saturday night and arrived at Dover at 2.40 on Sunday morning. Captain Romyn described the results so far beyond anything which the Belgian authorities had anticipated. A message was transmitted from Ostend to La Panne when the *Princess Clementine* left the Belgian port, and telegrams continued to be exchanged between the vessel and the shore at frequent intervals during the voyage to Dover. The messages were transmitted at the rate of about twenty words a minute. Messages were exchanged right up to the time the vessel reached Dover.

THE *Indian Meteorological Memoirs* (vol. xi. Part II.) contain a discussion of the observations recorded during the solar eclipse of January 22, 1898, at 154 meteorological stations in India, by Mr. J. Eliot, F.R.S. The weather was very fine over India generally, but at some of the more southerly stations the sky was overcast. The cooling effect of the eclipse was marked over the whole area; the maximum decrease of temperature ranged between 8° in the belt of totality to 4° in the extreme north and south, the maximum decrease occurring about twenty minutes later than the maximum obscuration of the sun. The movement of the air was very light generally, and was practically suspended during the greater part of the eclipse, but a noteworthy feature was the occurrence of a short, sudden gust about twenty minutes after the commencement of the eclipse at the majority of stations in and near the belt of totality. There was a remarkable increase in the amount of aqueous vapour, which commenced about the middle of the eclipse and was followed by an equally rapid decrease. This last feature was the most remarkable and unexpected phenomenon of this eclipse; it was exhibited at all stations, and was most pronounced at stations in the interior, on and near the line of totality. The diurnal variation of pressure was also considerably modified, the decrease of the amplitude averaging about ·035 inch.

AT the request of the Austrian Ministry of Agriculture, various experiments have been made by Drs. Pernter and Trabert with the view of testing the use of Mr. Stiger's apparatus for dispersing hail-clouds by gun-firing. The apparatus consists of a mortar with a long funnel fixed to the orifice; upon firing a sufficient charge of powder, rings or whirls are formed in the air and can be followed either by their hissing sound or by the particles of smoke carried up with them. The force and durability of the whirls vary with the charge, and with the size of the funnel, but it does not appear from the experiments that a greater altitude than about 400 metres was reached, which is much less than had been previously stated. It does not seem probable, therefore, that unless the hail-clouds are very low that any practical result is likely to be attained. The most that can be said in favour of the process is that while in some cases the formation of hail may have been prevented by the disturbance of equilibrium, hail frequently falls, in spite of frequent firing. The particulars of the experiments will be found in a recent number of the *Meteorologische Zeitschrift.*

DR. GOLDSCHMIDT, of Essen, has recently described a new welding process invented by himself (says *Fielden's Magazine* for October). The heat required is obtained by means of a compound called "Thermit." Metallic oxides, with aluminium, are its constituents, and it has the property of allowing a fusible mass at a high temperature to be quickly and simply produced. Its use in welding pipes and rails is its most interesting application, as, with its aid, rails can be welded immediately and economically and at any place, a melting-pot only being required. The details of the process are stated as follows:—"The melting-pot is filled with tar-oil, an inflammable mixture is added, and a match is used to ignite it. Spoonfuls of 'Thermit' are then added, which immediately ignites and produces temperatures as high as 3000° C. The highly incandescent contents of the pot consist of iron, called alumino-thermo-iron, on the top of which floats melted carborundum. An aluminium oxide is then poured on to the part of the rail to be welded, and the work is done so quickly that the melting-pot is cold and can be taken into the hand after being emptied."

SOME interesting observations on dielectric hysteresis have been lately published by M. F. Beaulard in the *Journal de Physique.* With condensers of paraffin and mica, little dissipation of energy by hysteresis was found, but with dielectrine, curves of hysteresis of the well-known forms were obtained. It was found, however, that the area of the curves and therefore the absorption of energy, varied with the period of time in which the cycle was performed, being less for slow than for rapid cycles. All this, the author considers, is explicable on M. Bouty's hypothesis, according to which the electric residue is due to a temporary retardation of the fictive polarisation on the polarising field. It is to be remarked that M. Pellat has rendered Bouty's explanation independent of the notion of fictive polarisation by proving the existence of a real polarisation varying with the time, thus explaining the phenomena observed in the present experiments, without assuming the existence of hysteresic properties in dielectrics analogous to those in magnetised bodies.

IN the *Bulletin* of the Cracow Academy, experiments are described by Constantin Zakrzewski on the electromotive force produced by the motion of a liquid through a silvered glass tube. The tube in question was a capillary tube connecting two large glass vessels half filled with water, and the electrodes terminated in the water at a short distance from the end of the tube. The flow of water was brought about by introducing compressed air into one of the vases. A current of water was always found to be accompanied by an electric current the direction of which depended on the water current, and the electromotive force was found (i) to vary as the difference of pressure at the ends of the tube; (ii) to depend on the distance of the electrodes from the ends of the tube, the effect of increasing this distance in the case of the electrode opposite the entering stream being to decrease the electromotive force. It is suggested that this result confirms the hypothesis of Quincke and Helmholtz, according to which the electromotive force has its origin in a kind of tearing of the layer of contact electricity between the silver and the water. The electromotive force depends on the thickness of the silvering, and decreases when the thickness increases. In the case of a solution of nitrate of silver, the electromotive force vanishes and changes sign when the concentration is equal to 1/3000 of the normal.

ABOUT three years ago, Dr. Folgheraiter published a description of observations of the "distinct" points and zones in the magnetisation of rocks, and showed that these singularities, of which he had observed a number in the Campagna, were due to lightning discharges. In a recent issue (No. 10) of the *Frammenti concernanti la geofisica dei Pressi di Roma*, the same author gives an account of certain measurements made with the object of determining (1) to what distance the magnetism produced by lightning produces any sensible action; (2) the direction of the magnetising lightning-discharge. The results already arrived at show that in certain singular zones (*zone distinte*) the direction of discharge is determinable, and the magnetic properties and distribution of magnetism resemble those of an ordinary magnet; while in the case of other zones it has been impossible, as yet, to ascertain either the direction of the magnetising discharge or the position of one of the two magnetic poles.

IN a recent number of *Terrestrial Magnetism and Atmospheric Electricity* (v., 2), Mr. William Sutherland puts forward a possible cause of the earth's magnetism and a theory of its variations. The cause suggested is the rotation of the electrostatic field within the earth, as Rowland's experiments have proved that a moving charge of electricity produces a magnetic field analogous to that of a current. If the earth carries round an electrostatic field in its rotation, then it will have the axis of its magnetic field identical with the axis of rotation, which is the chief approximate fact of the earth's magnetism. The actual obliquity of the magnetic to the rotational axis is traced to unsymmetrical magnetic permeability of the earth, which also causes the induction of earth currents, the secular variation of whose tracks is the cause of magnetic secular variation. The theory advanced to account for daily variation is that, under the action of the sun's rays, the oxygen and ozone of the atmosphere become the active substance of a large secondary battery or accumulator, whose alternate charge and discharge are the cause of the daily variations.

THE metamorphic rocks in Eastern Tyrone and Southern Donegal have engaged the attention of Prof. Grenville Cole, who has sought to determine the relative ages and relations of the granites and gneisses (*Trans.* Royal Irish Acad., vol. xxxi. Part ii. 1900). The oldest recognisable rocks in the two areas are schists foliated by dynamic metamorphism. In Eastern Tyrone, the occasional gneissic character of this schistose series has probably been induced by the intrusion of a granite magma, while the structures due to dynamic action have usually been lost in the new flow-structures set up. The gneisses, as well as the less altered schists, are traversed by and included in the granite of the Slieve Gallion type, which also cuts an overlying basic igneous series. In Tyrone, the older granitic material has not been exposed, but it appears in Southern Donegal, and there the granitoid gneiss is seen to be intrusive in an amphibolite series. The pure quartz-felspar-muscovite gneiss becomes rich in biotite at the junctions, and receives a foliated structure, which is due to flow and not to pressure-metamorphism. Similar relations have been observed elsewhere among the older metamorphic rocks. The Irish rocks, to which attention is now drawn, may all be of Archæan age, although the schists (termed Dalradian) are probably the oldest now remaining in the district. After referring to Dr. Callaway's researches in Galway, where he showed how gneiss has been formed by the intrusion of granite into a series rich in amphibole, the author remarks that his own observations tend to confirm the opinion that gneisses may be produced by admixture along surfaces of igneous contact, and that in such cases contact-metamorphism occurs upon a regional scale. Too often, however, the contact-phenomena on a broad scale have been removed by denudation from the surface of our granite domes, and we encounter them only in section along the flanks of the igneous mass.

THE official report of the polar expedition of the Duke of the Abruzzi is summarised in the *Times.* The following points are of interest. The *Stella Polare* left Christiania on June 12, and the farthest north point reached by it was 82° 4′. After this thet party had left the ship and established themselves on Rudolf Land. The Duke organised short excursions inland, in preparation for the great sledge expedition it was intended to undertake later. During an excursion at Christmas time the Duke and Cagni fell into a crevasse. The result of this was that two fingers of the Duke's left hand were incurably frostbitten, and the terminal joints had to be amputated. The shock of the fall and of the amputation affected the Duke's health so much that the doctor considered he was totally unfit to undertake the command of the expedition over the ice towards the Pole. Captain Cagni started on March 11, with a party consisting of ten officers and men, with numerous dogs and some sledges and kayaks. After nine days' march, during which 43½ miles were made, Cagni, finding the provisions running short, sent back Lieutenant Querini with two men. These three have not been heard of since. On March 31, when the sledge expedition had passed the 83rd parallel, Dr. Cavalli-Molinelli was sent back with two men. This, with two sledges and sixteen dogs, arrived safely at the main camp on April 24, having taken four days longer to return than to go. Cagni, in the meantime, continued his journey with three of the Italian Alpine guides. They were able to increase their speed to 9½ miles per day, and at last they reached Nansen's furthest north, 86° 14′. After a long and careful observation to make sure of this, they passed beyond, and on April 26, 1900, they touched 86° 33′ N. at about 56° E., when they decided to turn back. No land was in sight, nothing but ice in a state of thaw. Petermann's Land, which Payer believed he saw, did not exist where he stated, otherwise Cagni would have seen it early in his journey. The same is said of King Oscar Land, which would otherwise have been seen on the return march.

WE have received the November number of the *Entomologist's Monthly Magazine*, which contains notes on the occurrence in Britain of several rare Lepidoptera during the past summer.

THE *Transactions* of the Hull Scientific and Field Naturalists' Club for 1900 contain a number of papers and notes dealing with local natural history and antiquities, among which may be

mentioned one by Mr. T. Sheppard on prehistoric man in Holderness.

THE publishers have sent us the third part of Dr. Otto Fischer's elaborate treatise on the walk of man ("Der Gang des Menschen"). This section of the work, which is illustrated with seven plates, is devoted to a review of the scope of the whole investigation, and a summary of the movements of the lower limbs.

IN addition to a note by Mr. R. Hall on the change of plumage in certain birds, the August issue of the *Proceedings* of the Royal Society of Victoria (vol. xii. (n. s.), part I) contains no less than seven papers dealing with various groups of the invertebrate fauna of the colony. Two of these—on Isopod freshwater crustaceans—are by Prof. O. A. Sayce, each containing the description of a new genus. In a paper on the earthworms of the colony, Prof. Baldwin Spencer has to record two genera and a very large number of species as new to science.

IN the July issue of the *Journal* of the Straits Branch of the Royal Asiatic Society, Dr. R. Hanitsch gives an account of his recent expedition to Mount Kina Balu, British North Borneo, together with a summary of its zoological results. The examination of many of the specimens acquired was undertaken by specialists in England and Calcutta; and among the novelties are a new genus of freshwater fish and one of snakes, as well as two other new species of reptiles and one of batrachians, all these having been described by Mr. G. A. Boulenger. The paper is illustrated by two excellent photogravures of Bornean mountain scenery, as well as with two plates of the new reptiles, batrachian and fish. A second paper by Dr. Hanitsch deals with a flying frog of the genus Rhacophorus; and Mr. H. N. Ridley contributes a note on the use of the slow loris in Malay medicine.

WITH the commencement of the current volume of the *Botanical Gazette*, Prof. J. C. Arthur has vacated the editorial chair, which he has occupied since 1886. The responsible editors are now Prof. John M. Coulter and Prof. Charles R. Barnes.

WE have received a prospectus of the County School of Horticulture, Chelmsford, established by the Essex County Council, under the direction of Mr. David Houston and Mr. Charles Wakely. Instruction is given in the various branches of scientific horticulture, and certificates of proficiency are awarded. The technical instruction committee offer free instruction, travelling allowance, and, at their discretion, board and lodging, to fifteen pupils from the county of Essex, to be selected from candidates who fulfil the necessary conditions. Scholarships are also awarded, tenable for two years at the gardens of the Royal Horticultural Society, Chiswick, or other gardens approved by the committee.

NOW that the new Imperial Agricultural Department is settling down to steady work under Dr. Morris, the issue of the series of publications intended to supply colonial cultivators with the latest information on questions of interest to them is becoming more regular. The fourth number of the *West Indian Bulletin*, which has just reached us, is a double number, of 136 pages, in which Mr. Maxwell-Lefroy, the entomologist to the Department, deals with "Moth Borer in Sugar Cane"; Prof. d'Albuquerque and Mr. Bovell describe "Sugar Cane Experiments at Barbados"; Mr. Scard describes "Some Experiences with Seedling Cane in British Guiana"; the Hon. Francis Watts, "Tree Planting in Antigua" and "Care of Pastures in Antigua"; and Mr. J. H. Hart, "Some Fungi of the Cacao Tree." In addition to these contributions there are others on "Sugar Cane Experiments in Louisiana"; "The Fixation of Atmospheric Nitrogen by Leguminons Plants"; "Cacao Industry in Grenada"; "Agricultural Education in English Rural Schools," also in French rural schools; and "Fumigation of Seeds and Plants." Some of the articles are suitably illustrated. It is to be hoped that the planters and others in the various islands are making a careful study of the valuable facts thus brought to their notice by the Imperial authorities, and that they are recognising the absolute necessity of introducing more modern scientific methods into their systems of cultivation and preparation of goods for market, otherwise they must inevitably suffer in the keen competition with those who adopt all the latest discoveries of science to aid them in their calling.

WE have received from Prof. Francesco Porro, of Turin, a reprint of a note communicated by him to the *Giornale di Matematica* (Naples: B. Pellerano, February), containing a simple exposition of the problem of the motion of a planet about the sun. The paper is based on the methods adopted in Prof. Porro's university lectures.

THE September number of the *Physical Review* contains a photogravure frontispiece of the late Thomas Preston, of whom "E. M." contributes a short biography. It also contains a *résumé* of our knowledge of Becquerel rays, by Mr. Oscar M. Stewart.

MM. J. B. BAILLIÈRE ET FILS, Paris, have just published a "Catalogue général de Livres de Science" comprising the titles of books on all branches of physical and natural science. The catalogue contains more than five thousand titles, and reference to its contents is made easy by a detailed index.

MESSRS. ROBERT BOYLE AND SON, LTD., have issued a catalogue of lantern slides for lectures on ventilation, which they are prepared to lend, free of charge. The slides illustrate chiefly the Boyle system of ventilation applied to buildings of various kinds.

AN acetylene generator designed for use with optical lanterns, is included in Messrs. Newton and Co.'s supplementary list of lantern slides for the session 1900-1901. Among the new slides are sets illustrating the methods and results of eclipse observations made by Sir Norman Lockyer's expeditions of 1896 and 1898, Prof. R. W. Wood's photographs of sound waves, and Dr. J. L. Williams's photo-micrographic studies of the morphology and pathology of enamel of teeth.

A NOTEWORTHY characteristic of recent catalogues of many scientific instrument makers is the cheapness and simplicity of a large number of the instruments mentioned and illustrated. The catalogue of electrical apparatus and accessories just issued by Messrs. W. and J. George, Ltd. (late Messrs. F. E. Becker and Co.) is no exception to this commendable feature. Formerly it took years for a good piece of apparatus to find its way into an instrument maker's catalogue, but now the apparatus often becomes available a few months after it has been shown at a scientific society. We notice in the present catalogue, in addition to the usual instruments for lecture-rooms and laboratories, Davidson and Headley's localisers for Röntgen ray work, apparatus for Tesla's experiments with alternating currents of high frequency, and for Hertz wave experiments and wireless telegraphy.

MR. THOMAS MURBY has recently issued new editions of three text-books of science published by him. Prof. Meldola's book on "Inorganic Chemistry," which originally appeared twenty years ago, has been brought more or less into line with the present position of chemical science by Mr. J. Castell

Evans. The chapter on spectrum analysis might with advantage have been revised by some one familiar with recent work. The statement that "450 of the Fraunhofer lines have been observed to coincide with the lines of the iron spectrum," is, like several others, far behind the times, for more than 2000 coincidences have been photographed. A new edition (the tenth) of Skertchly's "Geology" has been prepared by Dr. James Monckman. A new section on petrology has been added to make the book suitable for the present requirements of the examiners of the Board of Education (South Kensington). A few alterations have been made, but the revision is not entirely satisfactory. For instance, a page is devoted to observations made by Mr. W. J. Henwood in 1871 on the temperatures of mines, although an excellent summary of such observations, containing far more instructive information, was given by Mr. Bennett Brough before the Society of Arts four or five years ago, and might have been used. A table of determinations of the earth's density is given, but it does not contain any of the observations made during the last ten years. Lord Kelvin remains Sir William Thomson; and only his early conclusions, and Helmholtz's, are given concerning the age of the earth. The figures, as well as many of the facts, are old-fashioned, and Dr. Monckman would have done better to have rewritten the book from the point of view of the geologist of to-day instead of attempting to adapt past ideas to present positions. Mr. Frank Rutley's little book on "Mineralogy" has deservedly had a successful career, and the twelfth edition, which Mr. Murby has just published, is a veritable *multum in parvo* as regards information of service to elementary students of mineralogy. Among the changes are the addition of a brief outline of the recently adopted treatment of crystal symmetry, a few figures of crystals, and the revision of the chemical formulæ.

THE additions to the Zoological Society's Gardens during the past week include two Patas Monkeys (*Cercopithecus patas*, ♂ ♀) from West Africa, presented by Mr. E. Jones; a Syrian Bear (*Ursus syriacus*) from Western Asia, presented by Mr. Robert de Rustafjaell; a Peregrine Falcon (*Falco peregrinus*) from Canada, presented by Mr. T. H. Small; an Osprey (*Pandian haliaetus*), captured in the Red Sea, presented by Captain T. Yendell; a Bush Dog (*Icticyon venaticus*, ♀) from Colombia, a Tayra (*Galictis barbara*) from South America, a Vervet Monkey (*Cercopithecus lalandii*) from South Africa, three Wattled Honey-eaters (*Anthochoera carunculata*) from Australia, deposited; a Bosman's Potto (*Perodicticus potto*) from West Africa, a Bouquet's Amazon (*Chrysotis bouqueti*) from Dominica, two Ruddy Sheldrakes (*Tadorna casarca*, ♂ ♀), two Knots (*Tringa canutus*), European, purchased.

OUR ASTRONOMICAL COLUMN.

THE PLANET EROS.—A good opportunity will be offered for detecting this little object on the early evenings of November 10 and 11 before moonrise. The planet will pass near the 5th magnitude star, 4 Persei, the positions of the objects being as follows:—

	R.A. h. m. s.	Decl. ° ′
4 Persei	1 55 38 ...	+54 0
Eros, November 10 ...	1 56 53 ...	+54 21
November 11 ...	1 54 51 ...	+54 19

The position for 4 Persei is for 1900. The places of Eros are for Berlin mean midnight, corresponding to G.M.T., 11h. 7m.

On November 10 Eros will be about ½° N.E. of the star, and on November 11 about ½° N.N.W. of the star. The magnitude of the planet will be 9½. If the small stars in the region indicated are carefully watched, Eros may soon be identified by his motion.

EPHEMERIS OF COMET 1900*b*.—The following is an abridgment from a complete ephemeris communicated by Herr A. Wedemeyer to the *Astronomische Nachrichten* (Bd. 153, No. 3670).

Ephemeris for 12h. Berlin Mean Time.

1900.	R.A. h. m. s.	Decl. ° ′ ″
Nov. 8 ...	15 26 1·69 ...	+66 7 1·6
10 ...	29 5·06 ...	66 17 18·7
12 ...	32 10·10 ...	66 29 12·3
14 ...	35 16·92 ...	66 42 41·4
16 ...	38 25·58 ...	66 57 45·0
18 ...	41 36·22 ...	67 14 22·2
20 ...	44 48·90 ...	67 32 31·9
22 ...	48 3·70 ...	67 52 12·5
24 ...	51 20·75 ...	68 13 22·8
26 ...	54 40·11 ...	68 36 1·5
28 ...	15 58 1·85 ...	69 0 6·5
30 ...	16 1 26·23 ...	+69 25 35·9

NEW VARIABLE STARS.—In the *Astronomische Nachrichten* (Bd. 153, No. 3669), Herr Jos. Hisgen, of the Valkenburg Observatory, announces that he has detected variability in a star in Cygnus having the following provisional position:—

$$\left.\begin{array}{l}\text{R.A.} = 19^h\ 43^m\ 19^s.\\ \text{Decl.} = +48^\circ\ 49'{\cdot}3\end{array}\right\}(1900{\cdot}0)$$

The star reaches the 9th magnitude, and the light changes comprises at least *four* magnitudes: an approximation to the period is given as about 250 days.

IN the *Astronomische Nachrichten* (Bd. 153, No. 3670), Dr. T. D. Anderson announces the variability of a star in Pegasus, the change of which has hitherto escaped notice. The position is as follows:—

$$\left.\begin{array}{l}\text{R.A.} = 22\text{h. } 4{\cdot}6\text{m.}\\ \text{Decl.} = +13^\circ\ 38'\end{array}\right\}(1855{\cdot}0).$$

The variation in magnitude is not completely stated, but at its maximum brightness the star is about 9·9 magnitude, while at minimum it was invisible in a 3-inch telescope.

IN the same issue of the above journal, Mr. A. Stanley Williams calls attention to a new variable star in Lyra with the following co-ordinates:—

$$\left.\begin{array}{l}\text{R.A.} = 18\text{h. } 32\text{m. } 51\text{s.}\\ \text{Decl.} = +43^\circ\ 49'{\cdot}6\end{array}\right\}(1855{\cdot}0).$$

The variation of magnitude was determined photographically from plates taken with a portrait lens of 4·4 inches aperture. When at its greatest brightness the star is of about 10·5 magnitude, diminishing to a minimum of below 12 magnitude. A table of successive observations indicates maxima to have occurred about December 31, 1899, and September 3, 1900.

ASTRONOMICAL WORK AT DUNSINK OBSERVATORY.—The ninth volume of astronomical observations and researches at Dunsink, the observatory belonging to Trinity College, Dublin, consists chiefly of a catalogue giving the mean places of 321 stars, furnished by observations made with the meridian circle during 1898-9, under the direction of Prof. C. J. Joly, the Astronomer Royal of Ireland. The instrument has been provided with a new reticle having three sets of five vertical wires instead of five sets as formerly. The actual observations and preparation of the catalogue were done by Mr. C. Martin.

THE LEONID METEORIC SHOWER.

WITH the return of the Leonid epoch we are naturally led to inquire as to the prospect immediately before us. The expectation of preceding years having been grievously disappointed, observers cannot help feeling very dubious as to the return of the meteors. This is accentuated by the fact that computations made under Dr. Downing's directions show that since their return in 1866 the denser part of the stream has been subject to considerable perturbation. At the middle of November 1899 the meteors probably passed about 1¼ millions of miles inside the earth's orbit, and therefore escaped a rencontre with the earth. At the ensuing approach the conditions appear even less favourable, for the calculations indicate that the swarm will pass us by at a point about 1⅝ millions of miles nearer to

the sun than the earth. There would seem therefore to be little chance of a rich display this year.

No one can question that the calculations so far as they go are perfectly trustworthy. But is it possible, in dealing with an enormous assemblage of meteors in respect of which our knowledge is admittedly very inadequate, to define either its position, extent or density with great exactness? There is still much of mystery involved in comets and meteors. It is just possible that some development or variation in the system of Leonids will bring it prominently into view again this year. At any rate, this must be regarded as a quite possible contingency, for it is certain that every feature connected with and influencing the visibility of the meteors cannot have been allowed for. Our historical knowledge of the various attributes of the stream is very rough and incomplete, for the swarm has only made one visible return since meteoric astronomy has been recognised as an interesting and important branch of astronomy.

But, whether or not the mathematical conclusions are justified or falsified by the experiences of next week, every one of us encourages the hope that a plentiful, if not a brilliant, display of meteors will be seen. And astronomers in every part of the world will look for it as a duty. Charts will be got ready for properly recording the paths; cameras will be put into position and every preparation made to suitably record the display should it put in an appearance. The event is not only magnificent as a spectacle, but it is capable of teaching us some valuable lessons.

The moon will offer some interference this year, as she rises on November 13 at 11h. 1m., on November 14 at 12h. 8m., and on November 15 at 13h. 13m., but she will be in her last quarter, so that her light will only obliterate the faintest class of meteors. She will, unfortunately, be situated near the Sickle of Leo. The planet Mars will be placed a few degrees north-west of Regulus. On November 14, at 5h., the moon and Mars will be in conjunction, the latter being 7½ degrees north.

If the shower proves strong or feeble it should be attentively watched on the three nights of November 13, 14 and 15, if the weather is sufficiently clear for the purpose. Regular meteoric observers will also endeavour to trace some of its meteors on dates preceding and following those mentioned. It is not certain that the radiant moves like the Perseids, and we require more data with reference to the duration of the shower. Meteors certainly fall from the Sickle—and they are, presumably, true Leonids—between November 7 and 21. It will be important, therefore, to determine the exact place of the radiant on every night possible during the fortnight mentioned. This will be difficult this year on dates before the maximum owing to the strong moonlight, but it ought to be easy of attainment for a few dates after the 15th, for the moon rapidly wanes and the long nights permit of watches during the eight hours or so from the rising of the radiant at about 10h. 15m. to between 6 and 7 a.m.

The feature to which ordinary observers may usefully direct their attention, should the phenomenon recur under pretty bright aspects, is that relating to the time of maximum display and the number of meteors visible. They should be counted and recorded at, say, five-minute intervals, and registered on forms previously prepared for the purpose. Where several observers combine to effect observations they will, of course, look to different quarters of the sky and be careful to avoid numbering the same objects.

The radiant point at about the time of maximum can be well left to the care of those who have adopted the photographic method. We have already accumulated a large number of determinations by the ordinary eye method; we now require more correct values, such as it is hoped the camera will afford us.

There are many showers in the region of Leo which furnish streak-leaving meteors, and no object should be included in counts of Leonids if its direction of flight when carried backwards does not cut through the Sickle. The best of these circinal Leonid showers is at $154° + 40°$ from a point about 17 degrees north of the Leonid radiant.

While observers are watching for the Leonid display, it often happens that not only are a few bright Leonids seen, but several large meteors appear from minor radiants. It used to be the custom to term the latter "sporadic" meteors, but they belong to well-defined systems, the great majority of which have now been ascertained. In all cases where a fine meteor is seen its apparent path on the celestial sphere should be as carefully recorded as the circumstances permit, and the time of apparition noted. If this plan were followed in every case a number of multiple observations of the same meteors would be available for computing their real paths in the atmosphere. It is hoped, therefore, that this important feature of the work will not be neglected during the ensuing observations, for it need occupy little time, and will certainly provide some valuable material for after comparison and discussion. Last year, on the morning of November 15, there was a magnificent meteor many times brighter than Venus, and though it was well seen at five or six of the leading observatories in England, its path position was not particularly recorded at any one of them.

The most probable time for the recurrence of the shower will be on the night following November 14, and a watch should be commenced soon after the radiant has risen. As a rule, not many meteors are discharged from a low radiant; but what is lacking in numbers is often compensated for by appearance. The Leonids seen before midnight are usually very conspicuous, owing to their long paths, dense streaks, and apparently more gradual flights than those which appear at a later hour of the night, when the radiant has attained a fair altitude. For my own part, I certainly entertain the hope that the display will put in appearance on November 14, and that, though its splendour may fall far short of that of some previous returns, it may yet prove gratifying to those who have looked for the shower in vain during the last few years. In any case, it is to be hoped that the atmosphere will be favourable, for much depends upon the state of the sky; and it is important that we should ascertain in what strength the event returns.

W. F. DENNING.

THE NOBEL PRIZES FOR SCIENTIFIC DISCOVERY.

A BRIEF note upon the prizes endowed by the late Dr. Nobel has already been given (p. 11). A translation into English of the regulations under which the prizes will be awarded is given in *Science*, and the essential parts are here stated for the convenience of investigators unable to see a copy of the official document just distributed by the Board of Education.

The three corporations awarding the Nobel prizes are:

(1) The Royal Academy of Sciences, at Stockholm. The King is the protector of the Academy, which numbers 100 Swedish and Norwegian members and 75 foreign members. (2) The Swedish Academy, at Stockholm. The King is the protector. The members, exclusively Swedish, are limited to 18. (3) The Carolin Institute of Medicine and Surgery, at Stockholm. The number of professors is 22.

The Nobel endowment is based on the will of Dr. Alfred Bernhard Nobel, engineer, drawn up November 27, 1895. The stipulations are as follows:

"The remainder of the fortune which I shall leave shall be disposed of in the following manner: The capital, converted into safe investments by the executors of my will, shall constitute a fund the interest of which shall be distributed annually as a reward to those who, in the course of the preceding year, shall have rendered the greatest services to humanity. The sum total shall be divided into five equal portions, assigned as follows:

"(1) To the person having made the most important discovery or invention in the department of physical science.

"(2) To the person having made the most important discovery or having produced the greatest improvement in chemistry.

"(3) To the author of the most important discovery in the department of physiology or of medicine.

"(4) To the author having produced the most notable literary work in the sense of idealism.

"(5) To the person having done the most, or the best, in the work of establishing the brotherhood of nations, for the suppression or the reduction of standing armies, as well as for the formation and the propagation of peace conferences.

"The prizes will be awarded as follows: For physical science and chemistry, by the Swedish Academy of Sciences; for works in physiology or medicine, by the Carolin Institute of Stockholm; for literature, by the Academy of Stockholm; finally, for the work of peace, by a committee of five members, elected by the Norwegian Stortung. It is my expressed will that nationality shall not be considered, so that the prize may accrue to the most worthy, whether he be a Scandinavian or not."

Each of the annual prizes established by the will will be awarded at least once in the course of every period of five years, commencing with the year immediately following that in which the Nobel endowment enters on its functions, and the sum total of a prize thus awarded will in no case be less than 60 per cent. of the part of the yearly revenues disposable for the distribution of the prizes; neither can it be divided into more than three prizes at the most.

Immediately after the approval by the King of the statute of endowment, the corporations will designate the stipulated number of representatives, who will assemble at Stockholm and elect the members of the board of administration, who will have the management of the endowment fund at the beginning of the year 1901. The executors of the will will take appropriate measures to terminate the settlement of the succession. The first distribution of prizes for all sections will take place, if possible, in 1901. From the endowment resources will be deducted: First, a sum of 300,000 crowns (16,000*l.*) for each section—that is, 1,500,000 crowns (80,400*l.*) in all—which, with the interest commencing from January 1, 1900, will be used to cover, in proportion, the expenses of the organisation of the Nobel institutes in addition to the sum the board of administration shall judge necessary for the acquisition of a special site destined for the administration of the endowment and including a hall for its meetings.

The right of presenting proposals for prizes belongs to—

(1) Native and foreign members of the Royal Academy of Sciences. (2) Members of the Nobel committees for natural philosophy and chemistry. (3) Professors who have received the Nobel prize of the Academy of Science. (4) Ordinary and extraordinary professors of natural sciences and chemistry in the Universities of Upsala, Lund, Christiania, Copenhagen and Helsingfórs, in the Carolin Institute of Medicine and Surgery, the Superior Technical Royal School, as well as to the professors of the same sciences in the Stockholm High School. (5) Incumbents of corresponding chairs of at least six universities or high-schools, which the Academy of Science will select, taking care to divide them suitably between the different countries and their universities. (6) Learned men, to whom the Academy shall judge proper to send an invitation to this effect.

The invitations will be sent every year in the month of September. Proposals for the prize must be made before February 1 of the following year. They will be classified by the Nobel committee and submitted to the college of professors. The Nobel committee will decide which of the works presented shall be submitted to a special examination. The college of professors will pronounce definitely on the distribution of the prize in the course of the month of October. The vote will be taken in secret; if necessary, the question may be decided by drawing lots.

The right to present candidates for the Nobel prize belongs to the members of the Swedish Academy, the French Academy, and the Spanish Academy, which resemble the Swedish Academy in their organisation and aim; to the members of the literary departments of other academies, as well as to the members of literary institutions and societies analogous to academies; to professors of æsthetics, of literature and of history in the universities. This order must be published at least every five years.

ELECTRICAL ENGINEERING AS A TRADE AND AS A SCIENCE.[1]

I DO not intend to make this in any sense a report of the progress of our Institution during the last or any number of years. I shall not, therefore, give any account of the exceedingly good work done by Colonel Crompton and the active service corps of our Electrical Engineer Volunteers in South Africa. I shall not describe how we *fêted* our American cousins in England and France, or how they *fêted* us; nor what a wonderful success accompanied all that was attempted by us or by them or by M. Mascart and our French colleagues, although I cannot refrain from bearing my testimony to the great kindness of the Prince of Wales and the British Commission in so generously lending us the British Pavilion for our great reception, and giving us the use of one of its rooms for our office all the time of our visit to Paris.

My brother has tried to get me to introduce to your notice some novel ideas which have come to us during the last ten years in our business of lighting the city of Galway from a fairly constant water-power, using accumulators with a gas plant stand-by. It has almost come to be a practical idea to produce carbide of calcium in wet seasons and utilise it through the gas engine in dry seasons. I was also tempted to discuss the use of large gas engine plant at central stations; and another of several subjects in which I have been recently engaged has been the magnetic effect produced by systems of electric traction. But I have resisted temptation and have chosen a subject which seems to me much more important.

Your president's address is followed by no discussion. He is, therefore, privileged, but his very privileges cause him to address you with a greater sense of responsibility; he may say what he pleases, but he must be very sure that he has the best interests of the Institution at heart; the interests of the Institution as a whole, not the interests merely of a few members, and least of all ought he to think of his own interests. Nevertheless, your president speaks not as an omniscient judge, but rather as a very fallible, very prejudiced, one-sided man who, because he has devoted himself to one part of the work of this Institution, is certain to be unfair in his comments upon other parts of the work.

Your past presidents represent in this way all classes of members of this Institution. You have had scientific men, given some of them to calculation and some to experiment, and some to both; men who have advanced the study of pure science. You have had practical telegraph men, civil and military; men cunning in land and deep-sea telegraphy and telephony; men cunning in railway signalling. You have had electrical chemists. You have had manufacturers and users of all kinds of electrical appliances. You have had men who devote themselves to the teaching of electrical engineers, and who fully appreciate the fact that no good teacher ought to be out of practical touch with the profession. And nearly all of your past presidents have invented things which are now in practical use.

As each of these men has given you at least one address written from his own peculiar point of view, his prejudices are not likely to have done any harm to members who read the other addresses. I know, therefore, that you are good-naturedly prepared to give me plenty of rope. I can predict the twinkle of amusement in the faces of some of my friends when they learn that I am about to take up a subject on which we have had many debates.

In this address I mean to put before you this simple question: Is electrical engineering to remain a profession or is it to become a trade? Is this Institution to continue to be a society for the advancement of knowledge in the applications of scientific principles to electrical industries, or is it to become a mere trades union?

Of course, at the present time the outside public are willing to regard membership of this Institution as a symb[illegible] something more than the membership of a mere trades union. During the early growth of any trade, even such a trade as that of the plumber, it was really a profession. And a common trade may suddenly become a profession, if it suddenly begins to develop, as, for example, stone-masonry of a hundred years ago suddenly developed into civil engineering. Electrical engineering has been developed rapidly, so that in the past it has certainly been a profession and not a trade.

Again, we are an institution of engineers, and the general public are willing to class us with other engineering institutions —for example, the Institution of Civil Engineers. Now the title M.Inst.C.E. is a professional distinction which represents in civil engineering what F.R.C.S does in surgery, or M.R.C.P. in medicine. We owe a great deal to our association with, and recognition by, the Institution of Civil Engineers; our meetings are held in its rooms; many of our members are also its members; our proceedings are modelled on its proceedings.

Now this older Institution, governed by the best thoughts of the best British engineers, has laid it down that its associate members, that important class from which the higher class is mainly fed, shall have passed certain specified examinations in pure and applied science. I am not now suggesting that we ought to adopt this science examination method of admitting any kind of members to our Institution. I do not believe in the wholesale adoption of methods of working from another society. I am asking you early in my address to remember that this greatest of all professional engineering institutions, governed by practical men full of common sense, knowing the wants of their

[1] Inaugural Address, delivered at the Institution of Electrical Engineers on November 8, by Prof. John Perry, F.R.S., President.

profession well, insists upon a knowledge of science in its new members. If this recognition of science did not exist anywhere else in the whole world, I say that its recognition by such a thoroughly good professional society as that of the Civil Engineers ought to recommend it to all professional societies.

In Germany an enormous stride has recently been made in the raising of Engineering degrees to rank with the highest University honours. There is hardly one engineer of eminence in Switzerland, France or Germany who has not passed with honour through the classes of one of their great science Universities.[1] In Great Britain, within the last fifteen years, not only have great engineering schools been established in all the manufacturing towns, but even in Cambridge University there is one of the best schools of civil, mechanical and electrical engineering of which I know anything.

Before we think of imitating the Institution of Civil Engineers, we ought to reflect on certain fundamental distinctions between that Institution and our own, which at first sight seem to make us less professional.

There is a well-known unwritten rule of the Civil Engineers, to which there are only a few exceptions, that no contracting railway or harbour engineer can acquire the title of M.Inst.C.E. I think myself that it is a pity to draw a hard and fast line between consulting engineers and contractors. No doubt it simplifies the labour of the Council in its selection of candidates, but it gives rise to anomalies.

A man, who was once a civil engineer because he served a pupilage under his clever father, and who now is nominally at the head of his father's large practice, the real engineering work being done by many clever employees, this man may be a member. A contracting engineer who shows marvellous ability, not only in rectifying the mistakes of the designer of a large bridge or tunnel or reservoir embankment, but shows the power of Lord Kitchener in directing the work of thousands of men, so that no man need be idle, and the whole contract goes on like clockwork, and is finished well in the minimum of time, this man is ineligible. Now, in our institution, it has been recognised from the very first that manufacturers and contractors and their employees may belong to the very highest ranks of their profession. Of course, I do not mean men who simply receive the profits of businesses, or even men who merely work to obtain orders for themselves. I mean men who are not merely formally, but in reality manufacturing or contracting engineers. I mean men who, in dealing with standardised things, design new methods for quick, good, cheap production of such things. I mean men who improve old forms of things, possibly through their paid subordinates. I mean by a manufacturer fit to be a M.I.E.E., a man who might act as his own manager, and who, perhaps, has a wider outlook than on mere managerial duties. So long as a contractor or manufacturer is really an engineer, we know that we add to our strength with the addition of every such member.

But consider a contractor who only uses ordinary types of machines or electrical plant in well-known ways, surely he can hardly be said to be in the profession at all. Surely the one thing that differentiates us from mere tradesmen is that we do not follow mere rule of thumb methods; we think for ourselves, we weigh advantages and disadvantages. If every new installation required the same treatment as existing ones, the engineer would degenerate into a tradesman, and it seems to me that the electrical engineer ought to have a special fear of such degeneration.

In railway and harbour and river and sanitary engineering, in every new job, there are new difficulties to be dealt with. An engineer who designs many undertakings and sees them carried out must be a thoughtful man; he cannot help keeping himself acquainted with engineering principles, and so he is a professional man. So an architect finds that each new job requires all his experience. Every case that comes before a real physician or surgeon requires a somewhat different treatment from any old case. Every case brought before a barrister requires the exercise of all his past experience. In every case a *profession* implies the necessity for the exercise of all one's past experience; because the work one has to do is never the same as any work one has ever done before. And when I say past experience, I really mean certain general principles which one has always in one's mind, principles derived from all that one has done or seen or read about.

[1] I understand also that the great unions of manufacturers in *Germany* are about to make facilities for giving a year of real factory work to the Polytechnic students, thus perfecting the German system. In Japan we found great success in requiring students to spend their summer in real shops, their winters at college. In England it may be that we shall prefer to let apprentices have shorter factory hours than workmen, their masters being responsible for instruction being given in theory.

Electrical engineering is in a curious position. It owes its being altogether to scientific men, to the laboratory and desk-work of a long line of experimenters and philosophers. Even now the work going on in a laboratory to-day becomes the much larger work of the engineer to-morrow. When at length the laboratory experiment is utilised in engineering, we see that there is no other kind of engineering which so lends itself to mathematical treatment and exact measurement. Most of the phenomena dealt with by the electrical engineer lend themselves to exact mathematical calculation, and after calculations are made exact measurements may be made to test the accuracy of our theory. For a completed machine or any of its parts can be submitted to the most searching electrical and magnetic tests, since these tests, unlike those applied by the mechanical engineer, do not destroy the body tested.

Contrast this with the calculations it is possible to make in other kinds of engineering. The pressure of earth against a revetement wall is possibly 200 or 300 per cent. greater, or 50 to 70 per cent. less than what we imagine it to be in what some limited men call theory. We use factors of safety 5 or 10 or more on all kinds of iron structure calculations, because we are aware of our ignorance of a correct method of dealing with the problems. The civil engineer never has exactly the same problem as has already been solved. In tunnelling, earthwork, building, &c., in making railways and canals, he is supremely dependent on the natural conditions provided for him; the configuration of the surface of the ground, the geological formation, the structural materials available in the neighbourhood. The story of how the engineer has to study the endlessly different ways of interaction of water and sand and gravel is told by the troublesome bars at the mouths of rivers all over the world, by the difficulties of coast and river-bank protection, by the failure of sea walls and piers. But why should I make a catalogue of the different kinds of work done by civil engineers? Every one of them needs the exercise of general scientific principles due to much experience.

Now of all such natural difficulties the consulting or contracting electrical engineer is greatly independent. Give him a source of power, and tell him what is to be done; whether he is to light a town or a building, whether with arc or incandescent lights; whether he drives a stamp mill near a mine or a pump, or a machine tool, or a spinning frame, the electrical part of the work is carried out in much the same way. Natural conditions affect him mainly in the cost of transport of his materials and the cost of labour. He can make in an easy way the most careful calculations as to the best arrangement of his conductors and machines to give maximum economy, and except for this easy calculation his work is that of a mere tradesman. He is practically independent even of the weather. There are, indeed, some of us who grumble that this easy calculation is not made easier still, who prefer to make arithmetical guesses rather than exact calculation, because perhaps we like to see a little uncertainty introduced into the problem to make it more like a problem in civil engineering. I want members to see clearly that as times go on, as our electrical engineering work gets more and more cut and dried, the man who loses the power to calculate, who loses his grip of the simple theory underlying our work, must sink more and more into the position of a mere tradesman who has no longer the right to call himself an engineer.

An electrical engineer must have such a good mental grasp of the general scientific principles underlying his work that he is able to improve existing things and ways of using these things. It has become the custom to call this *theory*, and I suppose I must follow the custom. I should prefer to call it *Science*[1] or *knowledge*. Do you remember Huxley's definition of Science? "Science," he said, "is organised common sense"; and this is really what I mean. Well, calling it *theory*, the man who is

[1] What Falstaff said of the word "occupy" we have to say of the word "Science." It is used by many people out of its proper meaning and then condemned, so that one is getting afraid to use it. In Prof. Fitzgerald's splendid inaugural address to the Dublin Section of this Institution he says: "As has recently been pointed out to me by Dr. Trouton, it would be impossible to say the same contemptuous things of *knowledge* as are said of *Science*. In Germany the word used, 'Wissenschaft,' is the one corresponding to our word 'knowledge,' and there nobody of any sense could say that 'knowledge is all humbug,' as is here often said, and still oftener thought, of 'Science.'"

permeated by theory, whose theory is so much a part of his mental machinery that it is always ready for practical application to any problem, he is the real engineer. But you must not mistake me in this matter. Eighty per cent. of the men who pass examinations in mathematics, mechanics and electricity have very little of this theory. Fifty per cent. of the writers of letters in the engineering journals in which mathematical expressions occur have almost nothing of this theory in their possession. It is unknown to foolish men. Books alone, lectures alone, experiments alone, workshop experience alone cannot teach this theory. The acumen of a Q.C. may actually prevent a man from acquiring it. A man may have much of this theory, although he may never have listened to lectures, although he may dislike the sight of a mathematical expression. I have known men who might be called illiterate to possess much theory. I have known many men who might be called good *electricians* who are almost wanting in the theory necessary for the electrical engineer.

I am speaking only of theory. Of the other qualifications for an engineer I need not here speak; they are present to the minds of all of us. A man may have any amount of knowledge; he may know how to apply his knowledge, and yet he may not be able to apply the knowledge from a want of engineering *character*.

The engineer must be a real man; he must possess individuality, the power to think for himself. He must not be like a sheep, knowing only enough to follow the bell-wether. Over and over again in the last thirty years have some of us given our students much the same sort of advice that Baden-Powell gives to scouts in that excellent little book of his. If any of you have not read that book you ought to buy it at once, and you will there find that if a man is to think for himself he must possess all kinds of knowledge, he must be constantly picking up new kinds of knowledge.

Nobody can limit the value of any kind of knowledge, but still one may say that certain things are probably more important than others. To gain what we call "theory" a good general education is most helpful—mathematical knowledge is very helpful; laboratory and workshop experience are extremely helpful. There is one qualification which the electrical engineer must have and without which all other qualifications are useless, and if a man has it no other qualification is supremely important, and this absolutely indispensable qualification is that a man shall love to think about and work with electrical things. He must like these, not because of the money he can make through electrical contrivances, nor even, I think, because of the name he may make before the world—this would be mere liking or cupboard love which has no lasting quality. So long as we have men in this country who have the true love for scientific work of which I speak, so long shall we have a real profession of electrical engineering, for such men are always scheming new contrivances and improving old ones and utilising the services of all helpful people, and especially of capitalists. When we have reached a state in which nobody schemes new things because the existing things are perfect there will no longer be a profession of electrical engineering. Of all ideas surely that of having reached *perfection* is most hateful: the idea of exact knowledge, that nothing is unknown, that there is no need for thought and therefore that to think for oneself is a sin.

And so, although we are all agreed that much standardisation in our contrivances and methods is absolutely necessary for our competition with other nations, we must follow the Americans in this matter and take care that it does not destroy invention. Of course when things are really standardised, when we have our perfect Mauser rifle or dynamo or locomotive or traction engine or electrically driven stamp mill, a Boer can buy or even manufacture them if he has money, and he can use them as well as, or possibly better than, we can. But he is not an engineer. He uses things after the engineer has done his work upon them. A stoker, a common engine-driver, the guard of a train, these are not engineers. You must have noticed that the American engineers, who surely deserve the character of being practical idealists above all other engineers, are the men who are most imbued with notions of standardisation which lead to cheapness of manufacture, and they are also the men most alive to the necessity for occasional scrapping of types of machinery when they become even a little antiquated.

Our chiefs, the men who run us all, our real men at this Institution, may be called Practical Idealists. They have imagination and judgment and individuality. They have the imagination and enthusiasm of inventors, and yet they are more than inventors, for they can estimate the worth of their own inventions and control their imaginations. They are ready to receive all new things, and yet they are not carried away. They are radicals and yet they are conservatives. They have what Mrs. Beecher Stowe called *Faculty*.

A strong imagination well under control, surely it is the greatest of mental gifts. I look round me and wonder how many of us really have it; and how many of us are only dull music-hall loving men, who scorn novels and poetry, who live utilitarian, material lives, whose aim is merely to make money through electricity, who love it not for its own self, who cherish their "tuppeny-ha'penny-worth" of theory because it is sufficient for their immediate wants. Why, even the writers of leading articles in the daily papers can talk of the wonders of electricity and what may yet come to pass; and yet we who make machines and use them and switch the marvellous thing on and off and take all sorts of liberties with it—we are like Calibans oblivious of the wonders of the fairy isle—like soulless priests making a living in the temple of Isis—like Aladdins who rub our lamp only to get the necessaries of life.

Twenty years ago some of us were laughed at for our optimism, and yet everything that we declared then to be doable has now actually been done by engineers, except the thing which was then and is now declared to be the supremely important thing, namely, the electric consumption of coal. We say now, as we said then, "The applied science of the future lies invisible and small in the operations of the men who work at pure chemistry and physics." And think of the wonderfully rapid rate at which laboratory discoveries have been made in the last eleven years, and how as the years go on they become more and more numerous; and yet many of us plod along with our work seeing no farther than our noses. A year is now more pregnant with discovery than a hundred years used to be, and yet the protective stolidity of our ancestors is upon us and we think of the latest discovery as if it were really the very last that can be made. A thousand men are measuring and trying new things in laboratories all over the world. Some of them plodding and soulless; others of them with imagination and clearness of vision. Do you think that nothing is to come from all that work?

And is it not one of the most important functions of the engineer to do as Mr. Marconi has done, to convince capitalists ignorant of science that if the successful laboratory experiment is tried on the large scale, it must also be successful? And are we going to leave all this pioneering work, with all its possibilities of great gain, albeit with possible loss, to foreign engineers, when in most cases the scientific discovery has been made in England? Are we so lacking in the hope and faith which are born of imagination and science? And must we in the future, as in the past, have to rely upon the influx of the clever foreigner like Sir William Siemens? Must we, Boer-like, always depend upon our Uitlander population, Fleming and German, Hollander, Huguenot and Hebrew, for the development of our natural resources?

Some of the best engineers I know are so exceptional that one must class them with geniuses; they have faculty and character, and so they have become engineers, even under the most unfavourable circumstances. They have passed through ordinary schools and yet developed common sense. They were pitchforked into practical work, and their liking for the work, as well as some curious kind of instinct, led them to pick up all sorts of knowledge, which have become part of their mental machinery. They continue to pick up new kinds of knowledge when these become necessary for their professional work. Unfortunately, these men do not realise how exceptional they are, and they advise boys to go direct from school into works. They forget that the other 99 per cent. of men treated in the same way as themselves can only become the hewers of wood and drawers of water to real engineers. Treated in this way, average boys are just like so many sheep: they learn just what seems absolutely necessary and no more; their acquaintance with the scientific principles underlying their trade is a hand-to-mouth knowledge, which becomes useless when their trade undergoes development.

In 1867 I was an apprentice, and when in the drawing office and pattern shop I remember well how I was chaffed for studying such a non-paying, non-practical subject as electricity. When I published my first electrical paper in 1874 before the

Royal Society, and even for some years afterwards, the real students of electricity in England could be counted on the fingers of one's hands. Many of us remember the first gramme magneto machine that came to this country, a scientific toy, in 1874. How many engineers dreamt that a great new branch of engineering had been started? Even in 1878 engineers were as a rule quite ignorant of electricity, and since then every year, although newspaper writers have talked largely of the age of electricity, the men actually engaged in electrical industries have acted as if the greatest of changes were not perpetually going on in it. To be left behind, or to become camp followers, children of Gibeon, this is the usual fate of the men who scorn theory. In 1882-4 we used to have to pay men 200*l*. and 300*l*. a year because they had a slight knowledge of electrical matters. In 1884-6 these very men were not worth twenty shillings a week; they were weeded out of the profession, and their places were taken by men of better knowledge. Two or three years after, these better men were again found to have been weeded out, because men of still better knowledge were available. And so it has gone on ever since. Men learn just enough to get posts; they settle down in these posts and scorn theory. They actually forget what little theory they once did possess. They know a great deal about existing machines, but presently they discover that improvements have been going on, and that they no longer have a right to say that they belong to the engineering profession. In every year one has told men, "You will be left behind. See A and B and C. I told them three years ago, when their names were in everybody's mouths, that they would be left behind like their predecessors, and they laughed. Now I tell you and you laugh, and you also will be left behind. Yes, I know that you get a good salary or large fees, and your head touches the sky. Nevertheless, because you neglect theory and the simple mathematics, by means of which theory is made available in practical problems, you will have to take a back seat presently, for our profession is in its early youth and is growing rapidly."

Remember that I do not now refer to the few exceptional heaven-born engineers who, in spite of bad training, do manage somehow to pick up the necessary knowledge. I speak of the average men, many of whom are now living in the same old fool's paradise. They know enough for present needs; they scorn the simple principles which underlie all our work; they scorn the easy mathematics by which these principles are most readily employed in practical problems; they will have their reward.

Just think of what is occurring at the present time. In England we have cheap coal, and it can be carried easily. In Switzerland and other countries where there is no cheap coal the water-power had to be utilised and power had to be transmitted great distances electrically. This needed high voltage, and as it is difficult to get high voltage with direct current machines, alternating currents were used, and on account of motor troubles multiphase working has been introduced. What a revelation it was to almost all of us, that visit of a year ago to Switzerland! We saw enormous schemes of lighting and traction and power. We saw electric trains driven by distant waterfalls sandwiched in among ordinary trains keeping proper time on working railways. We had known that there were great schemes carried out in Germany and America and other countries, and yet all the machines were quite unfamiliar to us. We were very much like what engineers of 1870 would have been if suddenly brought into a generating station. Is it not a fact that some of us, said to be eminent and thought to be practical, asked questions and made remarks which showed that we did not know the most elementary principles of three-phase working. Is it then any wonder that the traction schemes now being developed in England, on lines that are certainly not the best for this country of their adoption, are altogether dependent on the use of foreign electrical machinery and employ foreign electrical engineers? I am not putting this altogether fairly, for municipal procrastination has prevented our development, and yet I am not putting it altogether unfairly. We know too little theory.

I am afraid that just now we are in a rather tight place. I would give something to know how we in this room are going to get acquainted with modern electrical engineering. Our usual way of learning is by actual handling of things. But if the millions of pounds' worth of machinery coming to England every year is all foreign, and is used mainly under foreign superintendence, our usual method of study is made very difficult. True, there are American and German, and, indeed, English publications which would give a knowledge of the theory, but not, I think, to the average English electrical engineer. I know of many men, twenty-five to forty years of age, who seldom come to our meetings, and who say they are silent in discussions because they cannot be understood; perhaps these men will find a way to save us all from being left behind. There is much more that I might say in this connection. An individual Englishman may be left behind other Englishmen, and all English electrical engineers may be left behind the rest of the world, but all electrical engineers of the world may even be left behind other appliers of science. It is not merely that the incandescent mantle of the gas engineer is improving and necessitates improvements in our filaments, but, in spite of the flourishing conditions of our factories just now, I could give many other illustrations of how we shall all suffer if we do not keep adding to our knowledge. Twenty years ago, when giving some lectures in Clerkenwell to workers in the then flourishing watch trade, I ventured to prophesy the decay of that trade. But I am afraid that the case of Jonah and Nineveh is the only one in which prediction of disaster led to reform. I venture on no prophecy, therefore, because it might harden your hearts.

Much of the evil we suffer from is due to our average young men being pitchforked into works where they get no instruction, as soon as they leave school. If ordinary school education were worth the name, and if schoolmasters could be brought to see that we do not live in the fifteenth century, if boys were really taught to think for themselves through common-sense training in natural science, things would not be so bad. But the average boy leaves an English school with no power to think for himself, and with less than no knowledge of natural science; and he learns what he calls mathematics in such a fashion that he hates the sight of a mathematical expression all his life after.

And what is the result? English engineers do make a wonderfully intimate acquaintance with the machines and tools that they work with, but when it comes to the manufacture of new things they do it by fitting and trying, by quite unnecessary expenditure of money through trial and error. A machine is made and tried, and then another better one, until a good result is arrived at. And this method did well enough in the past, and would do well enough in the future if only we had not to compete with foreigners who can really calculate. It is not all smoke; there is a real danger in this foreign competition unless we mend our ways. There is an absolute necessity for great change in English ways; but there are so many people interested in the maintenance of old methods of working; so many people who think they will lose their bread and butter if a change takes place; so much capital, scholastic and other, invested in our old machinery, that it takes a catastrophe to produce changes. Much of the strength and weakness of England has always lain in her conservatism. We have been talking of standardisation of machinery lately, so I may say that things have been standardised in England for a long time. Now to get all the good effect of standardisation, it is occasionally necessary to go in for wholesale scrapping, and it is this scrapping part of the business that we dislike in England. We here all know that the District and Metropolitan Railways might have been worked electrically years ago just as easily as they will be when we are allowed to begin upon them, but of course the scrapping of a lot of steam locomotives was a serious thing. The loss of experience to English electrical engineers, because of this hatred of scrapping, is leading to other incalculable losses. I understand that the whole generating and line plant—the whole machinery of the Boston tramways—has been scrapped several times since they first were driven electrically. Japan has scrapped all her old civilisation just as France did. During the century now dying Germany has made the most sweeping changes in her law and school legislation, and indeed in everything. England and Spain and China, how they differ in this respect, even from England's own colonies.

Of course it may be said that English customs have grown during centuries; they are well tried, and there is no pressing need for sudden alteration. I quite agree, but unfortunately this very perfection and fitness of our customs have bred in us a want of flexibility, so that in cases where a sudden change is really necessary, we are disinclined to make the change merely because it is a change and for no other reason.

No one has ever heard me speak of the decadence of England. When the greatness and the wealth, the manliness and the strength, the healthiness and good life of England are shown

forth to the as yet ignorant world in all their magnitude there will be some astonishment. But it is our duty to keep up our high standards. We must change what is bad when we know it to be bad, and not let bad things[1] continue to exist, parasitic growths, maintained because on the whole we are strong and healthy. You will perhaps think that this is a very serious exordium when I tell you that I have introduced it all on account of the state of mathematics in our profession. I feel a sort of degradation every time that I hear a successful, clever old member of this Institution sneering at mathematics. There is a plausibility about his statements ; he himself has been very successful in life without much help from mathematics ; but indeed his sneer is doing a great deal of harm to the younger members who admire his success, who forget that he has succeeded in spite of, and not because of, his neglect of mathematics.

Our knowledge of electrical phenomena must be quantitative to be of practical use ; we must be able to calculate. Mathematics is the science of calculation, and we must therefore be able to employ, and we all do necessarily employ, less or more mathematics every hour of our professional lives. The draper and the grocer and the housekeeper merely need arithmetic. Everybody now knows some arithmetic. Everybody can add and subtract and multiply and divide, and keep accounts in some simple sort of way. This is due to the fact that arithmetic is no longer taught in the old Greek method with its twenty-seven independent characters (for our ten figures), the study of which required a lifetime, so that only old men could do multiplication, and they not only needed many hours to do one easy bit of multiplication, but declared that if the art were not practised every day it could not be remembered. Reading and writing and ciphering are now taught to everybody. It used to be that only learned men and philosophers could read, write and compute. You will remember the charge that was brought against one of Shakespeare's characters, who was said to possess mere bookish theory without practical knowledge. "And what was he?" "Forsooth a great arithmetician." Nowadays, when everybody can compute, we should say of the possessor of mere bookish theory, "Forsooth he knows the calculus."

For in mediæval times things were taught in such a way that only a few men had a chance of knowing how to read, write and cipher. We have been compelled to change all that ; the pedagogue has, by compulsion, given up his mediæval methods of teaching in these things, although in all other matters he retains them. But a time has come when we see that ciphering is not enough mathematics for us to be familiar with, we need a little algebra, we need co-ordinate geometry, we need the differential and integral calculus. The pedagogue tells us that we must follow the orthodox course of study, which takes many years ; and some of us, many of us, who have followed the orthodox method, find that we have spent so much time and mental power upon it and its thousands of unnecessary tricks and contrivances and philosophy, that we can take in no more ideas. We cannot utilise our mathematics on engineering problems because we are too old and tired and *blasé* to comprehend these problems. Nevertheless we are the only people who know mathematics, and so we publish volumes of unmeaning and useless disquisitions on problems that we do not understand. Or we know just enough mathematics to be able to show our ignorance to experts, but quite enough to impress engineers with our knowledge ; and we know just enough about engineering problems to show our ignorance to engineers, but quite enough to impress mathematicians, and what we publish is merely as the crackling of thorns under a pot.

As for the man who does understand electrical problems, he remembers that there was a something called a study of mathematics at his school, that he did pass certain examinations with much difficulty and tribulation, that the subject had no real meaning to him even when he was supposed to know it, and he now hates the sight of anything that looks like mathematics.

I tell you, gentlemen, that there is only one remedy for this sort of thing. Just as the antiquated method of studying arithmetic has been given up, so the antiquated method of studying other parts of mathematics must be given up. The practical engineer needs to use squared paper. What is the use of telling him that he has taken an unauthorised way to the study of co-ordinate geometry, that he cannot approach it except through Euclid and modern geometry and geometrical conics and algebra and trigonometry? He says the youngest child can be made to understand diagrams on squared paper.

So again the idea underlying the calculus is one that every child, every boy, every man possesses and uses every day of his life, and there are useful methods of the calculus that might be taught quite quickly to boys, and which it would be a pleasure to boys and men to use continually in all sorts of practical problems ; but of course the subject of the differential and integral calculus is one that must come at the end of a long course of what is to the average boy utterly uninteresting and unmeaning mathematics. Indeed, the average boy never reaches the subject, whose very names, differential and integral calculus, are enough to drive him frantic.

Yes, the schoolmasters say that we must follow the mediæval rules of the game, and all sorts of fine things are said about them ; but as a matter of fact we only need to bring a little common sense to bear upon schoolmasters. At present most of us stick to our arithmetic as a safe and well-tried friend. We compute after the manner of the draper and grocer and housekeeper. In finding out what is the best size of conductor, or armature winding or core, or iron and winding of a field magnet, we calculate by mere arithmetic for one size and then for another ; perhaps we have weeks of arithmetical computation before we find the right size of thing to use, and we cannot frame general rules. And some foolish person who knows a little mathematics, works at the problem (as we ought to be able to do, but are not), and he frames a general rule and we laugh at it, and sneer at mathematics because he has probably left out of account the most important consideration. We know that the result is wrong, but we cannot say why it is wrong.

Then there are some far-reaching, labour-saving ideas that we simply cannot get into our heads at all ; we cannot comprehend them. Am I sinning against the rule as to good comradeship which exists here if I say that some of us are ignorant of the most fundamental facts regulating economy in arranging sizes of conductors? Suppose we find the total cost of installing a conductor of a certain length, using one square inch section of copper. We do the same thing for other sizes, and we plot total cost and weight of mere copper on squared paper. I do not care what system we adopt if it is the same system for all sizes, and if we buy our materials from the same manufacturers and use the same kind of labour, our points will lie very nearly in a straight line on the squared paper. Hence increased cost will be proportioned to increased weight of copper, and, indeed, increased total cost will be like the mere increase in the cost of copper, taking a slightly higher price of copper per ton. Some of us, ignorant of the elementary mathematics involved in the problem, think that the mistake has been made of assuming that the cost of an installed conductor is merely the cost of the copper in it, and, of course, he must feel that it is too absurd a mistake not to be laughed over. With an elementary knowledge of mathematics his mistake would be impossible, and without such a knowledge the clever electrical engineer is constantly discovering mares' nests in the investigations which he criticises.

I know of long misleading accounts of the results of good experimental observations which might have been described in a few clear words by the aid of elementary mathematics. I know men who spend on a particular problem ten times the amount of worrying thought that would enable them to master the easy mathematics that includes all such problems. Quite recently one of our most eminent members declared to me that he had not really grasped the reason for small economy at a power station when there is a small load factor until he studied the common-sense mathematical form which has been given in a recent publication. And yet he is a man who has heard much, and read much, and talked much on this subject.

Every electrical engineer has a correct idea of how a transformer acts, or how the E.M.F. in one of the coils of an armature of a direct current or other generator, or, let us say, a rotary transformer, changes during a revolution, and how the E.M.F.'s of all the coils are combined to produce currents in the external circuits. But through how much mathematical tribulation must most of us have passed from our state of ignorance to our present state of knowledge! It is no wonder that we are disinclined to the study of a new phenomenon which seems as if it

[1] Such as our wretched system of weights and measures. Oh, young America and Australia, is it wise to waste a year of every child's life, and years of the life of every business man, merely because we do it in England? You get many of your pedagogues from us, and of course they say that without cwts., qrs., lbs., and Latin declensions and Euclid, the mind cannot be trained. Do you believe them, or are you with open eyes making a great sentimental sacrifice?

might lead us through the like tribulation. The tribulation is least because it is suffered only once if we first learn the calculus method which underlies all our work; it is greatest if we get it up in a completely new-looking form in every new problem. I speak now of what is most difficult in our study, for there is thought required in applying the calculus method. Thus, for example, in multiphase work at the present time the best mathematicians wonder how it is possible for easy calculation to be made in such a subject. What we want just now is that an electrical engineer acquainted with three-phase current phenomena should be so much a master of ordinary easy mathematics that he has a chance of discovering a very simple way of putting the matter before us. At present calculation is easy but tedious, and, indeed, repellent; but I am perfectly certain that a competent man might quickly invent methods of calculation which are not only easy but short and thinkable. Mathematicians with the requisite electrical knowledge, again, may be lacking in sympathy and humour. I know a book of more than three hundred large pages on ordinary alternating currents, and all the information in it is given far more simply in two pages of another book with which some of you are acquainted. Possibly, just now, mathematicians who are electrical and who have common sense have too much other work to do, and we must wait their leisure.

The fact is, mathematics ought to be the natural language of the electrical engineer, and at present it is a foreign language; we cannot read or write or think in it. We are at the beginning of our development, like monkeys whose necessities have increased faster than their powers of speech.

Some of you are aware that a new method of teaching mathematics has recently been introduced in nearly all evening classes in science schools throughout the country.[1] I wish I could say that there was a prospect of its being introduced in all schools, for it seems to me that this would lead to the result that all young men entering works would be masters of that kind of calculation which is most important in electrical engineering; not merely a few men having this power, but the average men, just as average men can read and write.

I am addressing engineers, men who utilise the results arrived at by scientific workers, men whose profession is applied science. But surely if we are to apply the results arrived at by scientific men, if the laboratory experiment of to-day is the engineering achievement of to-morrow, we ought to be very much alive to all that is going on in the scientific world.

All men ought to be far more alive to the importance of scientific work. On the psychological side, it is perfectly exasperating to me to see how few are the men who know that Darwin has given a key to almost all the great philosophical problems of antiquity, and that there is a great mental development accompanying the more evident engineering development now going on in the world. Again, it is the fault of our methods of education that all our great men, our most important, most brilliant, best educated men; our poets and novelists, our legislators and lawyers, our soldiers and sailors, our great manufacturers and merchants, our clergymen and schoolmasters, should remain so ignorant of physical science, the application of which by a few men not ignorant is transforming all the conditions of civilisation.[2] But, of all men, just think what it means for engineers to be ignorant of science, or neglectful of its new developments; and, of all engineers, think what it would mean if electrical engineers sinned in this way.

Except ours, all other branches of industry have taken thousands of years to grow. There were bridge and hydraulic and sanitary and harbour and river engineers in ancient Rome, and such engineers existed thousands of years before the first papyrus was written in Egypt. But no Assyrian tile or Egyptian hieroglyphic or relic from a tomb indicates that telephones or electrical motors or electric lights existed before our time. No gradual improvement in our methods of conquering nature led up from small beginnings in our electrical engineering. Our profession has not grown during thousands of years of time, like other professions. It has sprung suddenly, full grown, from the new spirit which is going to rule the souls and bodies of men, the spirit of research in pure science. The new spirit puts knowledge, mere knowledge of nature, as its highest aim. The scientific student knows that all sorts of good must come to mankind from his studies; all sorts of scientific knowledge are sure to be utilised by engineers, but in the pursuit of science the usefulness and utility of the results are of no importance. And are we—we who have received the first-fruits of the labours of scientific men, we the first-born spoilt children of the great parent of all that is to come, we who form the foremost files of the present time—are we going to turn upon our beautiful young mother and say she is useless and ugly, and she hinders our money-making, and that we are willing to kill her for the sake of the burial fee? Thank God that is the spirit of only a few of us. Have we not as an Institution gone to great expense in the publication of *Science Abstracts* in partnership with the Physical Society? That publication has been and continues to be of the very greatest value to all students of pure and applied science who read our language, for it tells them the results of all the scientific work now being done in all parts of the world. And even if some of us do not read that useful publication, do we not know that it is there to read if we like? Do we not know that it is a symbol of our redemption from the yoke of the Philistine? It is one of many signs that in answer to the question which I have asked in this address, we can truthfully say that we are professional men, that our profession has promise of enormous expansion and improvement, and that we are not mere tradesmen.

I am afraid that you will think that I have a personal interest in putting before you the claims for consideration of the pursuit of pure science, because you know that I am trying to defend Kew Observatory from imminent danger. In truth I have no interest in this matter unbecoming a president of this Institution. For two years I have been trying to reason with traction engineers. Like many other electrical engineers these gentlemen desire to use uninsulated return conductors. If they do so near a magnetic observatory certain records of terrestrial magnetic disturbances are quite spoilt. At Potsdam this sacrilege has been forbidden. At Washington, Toronto, Capetown, and most other important places, the magnetic records have already been rendered useless. Professor Rücker and I were asked by the other members of the Committee of the Royal Society which was in charge of the Kew Observatory to defend Kew, and with the help of her Majesty's Treasury we thought we were able to insist upon the use of insulated returns in all undertakings authorised by Parliament where harm was likely to be inflicted on Government observatories. I may say that the scheme designed by Mr. Clifton Robinson for using an insulated return conductor in the working of the tramways of the London United Tramways Company, in consequence of our action, was a thoroughly good scheme which it gave one satisfaction to look at, not ugly and not expensive. It seemed to me a fit scheme for any tramway system, however complex, in which overhead conductors are used. You are aware that for an electric railway or for a tramway where a conduit is employed, it is in every way better, and is in a large scheme actually cheaper, to use an insulated return. We felt therefore very happy, for magnetic observatories seemed quite safe from interference. We were, however, mistaken, for the only clause which we have been able to get inserted in all Parliamentary authorisations of undertakings leaves it to the Board of Trade to substitute other methods of protection than the insulation of the return conductors in cases where these other methods seem to be sufficiently good for the protection of laboratories and observatories, and this is why the Board of Trade appointed the Committee which met on October 31 probably for the last time.

Prof. Rücker, Prof. Ayrton, and I have made many tests on the magnetic disturbances produced by tramways and railways, particularly by the Stockton tramways and by the Waterloo and City Railway, and we have had many meetings with the traction engineers, but nothing has yet been decided.

I mention this matter, which has given great anxiety to scientific men, because I am afraid that some of you may think when you hear of it that I have been acting against the interests of the electrical industry. I beg to assure you that I have been acting in your best interests. As an electrical engineer I ought surely to regret the use of uninsulated returns, even if we leave Kew Observatory out of account. Suppose we do not now insulate our returns. Electricity will certainly return by gas and water pipes, and

[1] See summary of Lectures on Practical Mathematics; also the Science and Art Directory, and the Reports of Examiners on the Science Examinations of 1899 and 1900, all published by the Education Department, South Kensington, S.W. The reforms now advocated in mathematical and science teaching are all clearly described in a paper read before the Society of Arts in January, 1880.

[2] See articles in NATURE of July 5 and August 2

the amount of harm done to those pipes is merely a question of time. Because of the ignorance of legislators and gas and water companies, nothing is said just now; but will nothing be said at the end of ten or twenty years, when pipes are found to be eaten away everywhere? And if by a slight increase of expense, or rather, as I think, actually no increase of expense, but merely a little increase in inventiveness and common sense on the part of electrical engineers, this evil may be entirely prevented, surely it is in the interests of all of us that insulated returns should be insisted upon. But even if we do not insist on insulating the returns in all systems, surely something may be said for the giving of this protection on lines near such a magnetic observatory as Kew. Even the magnetograph records now being made have been continuous for forty-five years, and if Kew is interfered with no sum of money can compensate for the interference; for if the Observatory were removed the future observations would have no link with the past.

An engineer in this room declared that it seemed to him an injustice to hamper the progress of electric tramways "for the sake of making observations that never have given, and never may give, to the world any important results." Now, it is not so much on account of Kew that I object to this sort of observation, as to its general spirit of antagonism to scientific research.

There is no doubt that the answer to the old question, which Gilbert might have asked three hundred years ago, "What is the cause of terrestrial magnetism?" is very jealously hidden from us by Nature. The earth probably contains much iron, but its great internal heat seems to forbid our imagining the iron to be magnetic. The assumption that a negative electric charge on the rotating earth will explain things requires such an enormous charge that this assumption has been discarded. There are annual and diurnal variations of a fairly regular kind; there are storms which have some relation to the Aurora Borealis, to sunspots and to earth currents. There are small sudden changes which seem to occur almost instantaneously all over the earth. Observations of these things may be useless from some points of view, but scientific men have been, and continue to be, willing to give up time and much money for this object. Utilitarians had to be cajoled through superstition to allow observations of the stars to be carried on in ancient times, and we have no such cajolery to offer. We simply say that it has been through this sort of useless-looking method of working that all our progress in science has come.

Engineers descended from men who sneered at Cavendish and Franklin and Volta and Oersted and Ohm and Faraday, are you who utilise the results of the work so sneered at, and pile up fortunes in consequence of it, are you the men to sneer at and ridicule the scientific work of the present day because it seems to you useless?

Tell us a better method of observation; give us better suggestions as to what these magnetic phenomena may mean; but the past record of scientific observation enables us to laugh at you when you say that magnetic observations may never give the world any important results. Was Nature ever so open and yet so closed about a secret as she is about this one of terrestrial magnetism? Was there ever one whose revelation promised so much? How very little we know of electricity and magnetism! Does the mere motion of the earth, taking no account of electric charges at all, cause it to be magnetic? Almost anything is on the cards. Surely I need not appeal to your cupidity, but it is quite possible that our knowledge of this secret may enable us to tap a tremendous store of Nature's energy.

Gentlemen, this is not a trades union, and it is not a society for the furtherance of pure scientific research, but it is a society of professional men who recognise the past services of scientific observers with gratitude and respect, and hope for greater ones in the future. And shall it be said of us that our gratitude is not greater than that of Judas, to whom indeed thirty pieces of silver was doubtless a large sum; that "we have given our hearts away a sordid boon"; and that as to our future hopes we are willing to sell our birthright for a mess of pottage?

THE NEW SCIENTIFIC LABORATORIES AT KING'S COLLEGE, LONDON.

On the afternoon of October 30 the new scientific laboratories at King's College were opened by Lord Lister, in the presence of the Lord Mayor and a large and distinguished gathering of men of science. Lord Lister, after his introduction by Dr. Robertson, the principal of the college, said the occasion marked an event of great importance in the higher education of the metropolis. The necessity of practical instruction to supplement mere lectures was now fully realised; and it was in order to satisfy this want in every particular that the new laboratories had been added to King's College. In many branches the college had long been well equipped for this purpose; the Wheatstone Museum in particular would bear witness to this; but the dissecting-room, and the accommodation for the practical teaching of physiology had been very defective. But now all this had been remedied; the bacteriological laboratory and the geological department had also received many improvements; and, in short, it might safely be said that King's College was now fully abreast of the age in the opportunities it afforded for practical teaching in all departments.

The Lord Mayor proposed a vote of thanks to Lord Lister; and in seconding, the Hon. W. F. D. Smith, M.P., treasurer of the college, stated that the new buildings, together with their equipment, would, when completed, cost 20,000*l.*, and reminded his audience that only one-fifth of this sum had so far been subscribed.

Lord Lister having declared the laboratories open, they were inspected by those present.

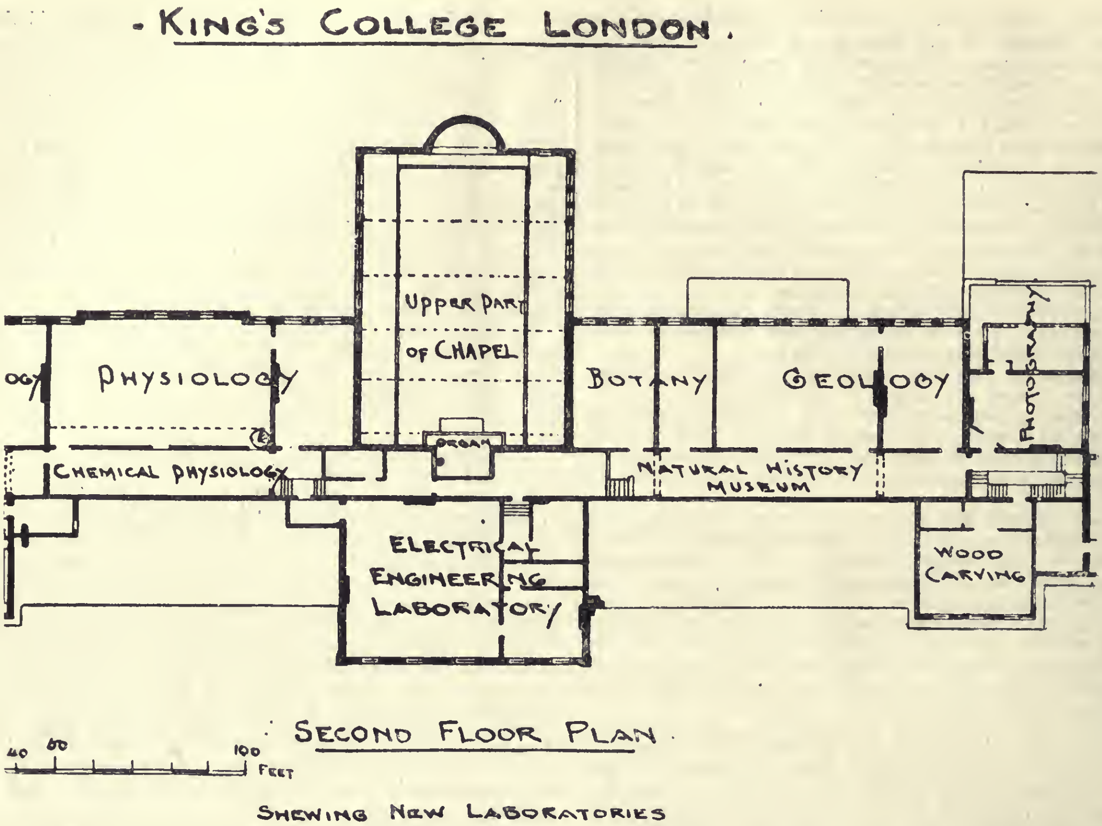
The laboratories are the result of a comprehensive scheme of extension and improvement of the teaching accommodation of the college, resolved upon by the council in the summer of 1899, and now practically completed. The biological, architectural, anatomical and mechanical departments have all benefited to a considerable extent by the new works, especially the departments first mentioned. The whole south wing of the college has been raised by an additional story, which includes the new geological, comparative anatomy and botanical departments, while the second story of the north wing, comprising the physiological and bacteriological departments, has been largely reconstructed, as has also the very fine room on the first floor now allotted to the architectural department. The reconstruction of the anatomical department and medical museum is also approximately complete, but the equipment is at present in progress.

The department of physiology comprises (1) a spacious central laboratory, seating over 100 students; the work tables are suited either for microscope work or for practical work in chemical physiology. There are in addition sixteen separate tables provided with shafting and all the necessary electrical apparatus for the study of experimental physiology, a branch of the science which is becoming every year of greater importance; (2) a large room for investigations in chemical physiology; (3) a spacious and well-fitted room for experimental physiology; (4) a dark room for photographic and galvanometer work; (5) a private workroom for the professor. These, with the necessary storerooms and accommodation for the laboratory attendants, make up a very complete suite of rooms.

In the anatomical department the dissecting room has been nearly doubled in size, and all the accessory rooms necessary in a well-equipped anatomical department are now provided. The section of the college museum which relates to pathology will also be housed in part of the old physiological rooms in the basement, and a new room has been built for the anatomical portion of the museum.

The department of bacteriology contains a practical classroom devoted to the technical education of post-graduate and other students from all parts of the world. Every student with his own hands goes through the whole practical course, and is further assisted by lectures and practical demonstrations. Several students have been especially trained with a view to investigating plague, cholera, yellow fever, madura and other tropical diseases, as well as the diseases of farm stock which are prevalent in our colonies and in foreign countries. In the technical laboratory, research work has been undertaken for the Board of Agriculture and for colonial Governments, while a number of workers have published researches on various bacteriological subjects. The new research room and library is used by advanced students and by the professor. A new feature is the bacteriological library of about 1000 volumes and pamphlets, lent by the professor for the use of the senior students. A lecture theatre has been built for the use of the bacteriological and physiological departments, and will accommodate about 200 students.

The general geological laboratory and lecture room will accommodate fifty students. The room is fitted both for lecturing



purposes and practical work, gas, water, and the electric light being laid on. In the practical class the engineering students are divided into several sections; one set of students use the petrological microscope, another set make blowpipe and chemical examinations of minerals, a third draw sections from geological maps, while a fourth set examine and draw fossils; the work of each class follows a regular schedule. The geological research laboratory is used by the professor and the more advanced students who wish to do original research. The room is fitted up similarly to the large laboratory, and contains a portion of the teaching collection and the nucleus of a library of geological works and reports.

FIG. 2.—The general laboratory and classroom in the Physiological Department.

The botanical laboratories consist of two rooms—the general laboratory for elementary work, and the research laboratory for advanced work and private research. The general laboratory provides table accommodation for twenty-four students, and is equipped with all the necessary appliances for the practical study of plants, either fresh or dry. The botanical research laboratory provides accommodation for twelve students. In this laboratory provision is made for the practical study of the chief physiological processes of plants, and for chemical investigations.

The materia medica and pharmacological collection of specimens used in teaching is contained in the upper part of the corridor, and is open to students for purposes of study; the lectures are given in another part of the building.

The Wheatstone Physical Laboratory is well equipped for delicate balance work, heat and electrical measurement, and the determination of the general physical constants. A new dark room for spectroscopic work has been specially constructed, and a room set apart for magnetic work.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The annual grant to the Botanic Garden has been raised to a sum which will make the income of the garden 670*l*., instead of 650*l*. as formerly.

The examiners for the Burdett-Coutts Scholarship in geology have not awarded the scholarship this year.

The Board of the Faculty of Natural Science have recommended that certificates should be issued entitling the following to supplicate for the degree of Doctor of Science:—Prof. Poulton, for researches on the influence of environment upon the colours of lepidopterous larvæ and pupæ; Prof. Turner, for researches on stellar photography; Prof. Miers, for researches on the red silver ores; Prof. Love, for researches on the theory of elasticity, theoretical mechanics, and the application of mathematics to physics; Prof. Weldon, for researches on natural selection; Mr. Hatchett Jackson, for researches on comparative anatomy and the morphology of lepidoptera; Mr. Lloyd Tanner, for researches on the theory of differential equations, theory of cyclotomic functions, &c.; Mr. F. A. Bather, for researches on fossil echinodermata, pelmatozoa, and blastoidea. These gentlemen will doubtless be the first to take the new research degree, which has at present only been conferred as an honorary degree.

CAMBRIDGE.—Mr. J. G. Leathem, St. John's College, has been appointed Chairman of the Examiners for the Mathematical Tripos, Part I.

Mr. R. W. H. T. Hudson, Senior Wrangler 1898, Smith's Prizeman 1900, son of Prof. Hudson of King's College, London, has been elected to a Fellowship of St. John's College.

A meeting for the purpose of establishing a memorial of the late Prof. Sidgwick is to be held in Trinity College Lodge at 3 p.m. on November 26.

The Vice-Chancellor has published a list of donations to the Benefaction Fund, bringing up the total to over 66,000*l*. Donations to the Agricultural Education Fund, for the special purpose of equipping the experimental farm, amount to nearly 1600*l*.

It is proposed to alter the regulations for Part II. of the Natural Sciences Tripos so as to permit of a candidate being placed in the first class provided he shows a sufficiently good knowledge of two subjects combined. Hitherto a first class has been awarded only for special proficiency in one subject.

DR. ERSKINE-MURRAY was appointed, at the beginning of the present session, lecturer and demonstrator of physics and mathematics at the University College, Nottingham.

THE extent of the work of the London Technical Education Board is shown in the current number of the *Technical Education Gazette*. Particulars are given of evening classes conducted under the auspices of the Board during the session 1900–1901, and though they are closely tabulated, the tables occupy 127 pages.

DR. OSCAR LOEW, for some time expert physiologist in the division of vegetable physiology and pathology of the United States Department of Agriculture, has resigned (says *Science*) in order to accept a position in the Agricultural College of the Imperial University of Tokyo, Japan, as lecturer on physiological chemistry.

SEVERAL months ago the Senate of the University of London asked the London County Council to give the name University Avenue to the road in which the university buildings are situated, now known as Imperial Institute Road. The governing body of the Imperial Institute has, however, strongly objected to the suggested alteration, and the County Council has decided to let the old name remain.

SPEAKING at St. George's Hospital on Tuesday, Sir Michael Foster referred to the inadequate provision made in our hospitals for the scientific investigation of disease. The analysis of the phenomena presented at the bed-side and in the *post mortem* room is not carried out as exactly, as completely, as fully, and as systematically as it might be. The use of the thermometer is a type of the exact analysis of clinical phenomena. In addition there is now chemical analysis, physical analysis, bacteriological analysis, but in none of our great hospitals is that analysis as complete, systematic, and exact as it should be. Such a complete analysis of all the phenomena in each case can only be carried on by means of thoroughly equipped laboratories in connection with the hospital—chemical, physical, biological, bacteriological, and other laboratories. In London the hospitals are less properly equipped in this direction not only than the hospitals of other countries, more especially America and Germany, but than even the hospitals of the provinces. It may or may not be desirable to attach to our hospitals chemical, physical and biological laboratories for the instruction of the student in introductory science; but each hospital ought to have its properly equipped clinical laboratories established for the welfare of the patient, the cost of which was as much a proper charge on the funds of the hospital as the bill for drugs or surgical appliances.

THE University College of North Wales has numbered, and still includes, among its professoriate the names of men of "light and leading" in the worlds of science, art and literature; hence its courses and laboratories, as described in the Calendar for the session 1900–1901, are worth examination. The physical, chemical, and biological laboratories occupy a large area, and the appliances provided are sufficient to enable the college to offer complete courses of work in their sciences. There is a department of electrical engineering maintained by means of an annual grant made by the Drapers' Company; and a course of lectures and experimental work, suitable for students of this branch of applied science, has just been commenced. Efforts are being made to establish a department of mining, and a conference in support of this object was held a few days ago at Rhyl. The conference was attended by representatives of the county councils, urban and rural district councils, and the technical instruction authorities of North Wales, as well as the owners and managers of mines, quarries, brick, steel and iron works in the northern half of the Principality. Students in the proposed department would, of course, attend the college lectures bearing upon their subject, but it would also be necessary to add to the staff a professor of mining and mine surveying, a professor of geology and mineralogy and an additional assistant lecturer in the chemical department, to take charge of the subject of metallurgy. It is estimated that, in order to meet the additional expense thus thrown upon the college, and for the proper maintenance of the new laboratories, an annual income of not less than 1100*l*. should be assured to the department. The establishment of mining and geological laboratories, and the provision necessary for the teaching of metallurgy would also render necessary a capital expenditure, including buildings, of about 8000*l*. All the speakers at the meeting, including Prof. Le Neve Foster, agreed in thinking that mining in North Wales would be benefited by the establishment of the department suggested, and resolutions were eventually adopted expressing support of the scheme, and pledging the conference to exert all possible means to carry it into effect.

THE work of the examinations department of the City and Guilds of London Institute is so extensive that the only satisfactory way to obtain an estimate of it is to read the annual report, which can be obtained for threepence from Messrs. Whittaker and Co., Paternoster-square, E.C. It appears, from the report just issued, that during the session 1899–1900 the total number of classes registered by the institute was 2460 as compared with 2087 in the previous session. The number of candidates' papers worked at the recent examinations was 15,557, as compared with 14,978 in the previous year, and whilst, only a few years ago, all the examinations were held on two days, they extended this year to twenty days. Mention has already been made of the desirability of closely associating the work of the technological department of the institute with that of the branch of the Board of Education dealing with technology. On August 24 an official announcement was made that an assistant secretary for technology had been appointed, and that "in the ensuing autumn it is proposesd to appoint a departmental committee, on which the County Councils and the City and Guilds of London Institute will be represented, to consider, *inter alia*, the co-ordination of the technological administration of the Board of Education with the technological work at

present carried on by educational bodies other than that board." Examinations are held in India and in several of the colonies as well as at home. The report shows that Bombay sent up this year thirty-eight candidates in cotton manufacture and dyeing, against eighteen last year. Earnest efforts are being made to provide technical instruction for operatives engaged in cotton mills in or near Bombay, and, with the further development of the cotton industry, the number of candidates from India who present themselves for the institute's examination is likely to increase. The work of the department also includes the direction of instruction and the conduct of examinations in technology and manual training. The instruction in manual training is intended exclusively for those who are preparing to become teachers in elementary or secondary schools. The difficulty of arranging for the special instruction in the methods of teaching, of which artisan students stand in need, has for some time engaged the serious attention of the institute, and, with a view of indicating the kind of lessons which it was thought desirable that County Councils might provide, a letter, enclosing a suggested scheme of instruction, was addressed in November last to the organising secretaries, and secretaries of local committees having manual training classes under their charge.

SCIENTIFIC SERIAL.

Bulletin of the American Mathematical Society, October.—Prof. F. N. Cole gives an account of the proceedings at the seventh summer meeting of the Society, which was held in June last at Columbia University, New York City. The occasion was one of the most successful in the Society's history, having been attended by upwards of fifty members. Abstracts are given of many of the papers read. These papers will subsequently appear either in the *Bulletin* or in the *Transactions*. In connection with this gathering, the final session was devoted to an organised discussion of the following question:—What course in mathematics shall be offered to the student who desires to devote one-half, one-third or one-fourth of his undergraduate time to preparation for graduate work in mathematics? An abstract of papers read by Profs. Moore, Harkness, Osgood, Morley and Young is given by Prof. W. H. Maltbie. The discussion suggests many points of interest. Prof. (Miss) C. A. Scott furnishes an interesting article on a memoir by Riccardo de Paolis. This mathematician about twenty years since published a series of memoirs dealing with the (2, 1) transformation of the plane (cf. *Atti d. r. Accad. dei Lincei*, vol. i. (1877) pp. 511–544; vol. ii. (1878) pp. 31–50; and pp. 851–878). An exhaustive treatment is given, and Miss Scott ends thus: "the intrinsic interest of de Paolis' work is surely excuse enough for devoting some little space to it" in the *Bulletin*. References are freely made to the writings of other geometers on cognate lines. The "Notes" are full of the "Courses in Mathematics" for the winter semester at most, if not all, of the German Universities. Other details of interest to mathematicians fill up the remainder of the number, together with a long list of recent publications.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 21.—"Energy of Röntgen and Becquerel Rays and the Energy required to produce an Ion in Gases," by E. Rutherford, M.A., B.Sc., Macdonald Professor of Physics, and R. K. McClung, B.A., Demonstrator in Physics, McGill University, Montreal. Communicated by Prof. J. J. Thomson, F.R.S.

The primary object of the investigations described in the paper was the determination of the energy required to produce a gaseous ion when X rays pass through a gas, and to deduce from the result the amount of energy radiated out into the gas by uranium, thorium and the other radio-active substances.

In order to determine this "ionic energy" it has been necessary to accurately measure the heating effect of X rays and the absorption of Röntgen radiation in passing through a gas.

The method adopted to determine the ionic energy was briefly as follows:—

The maximum current between two electrodes produced by the ionisation of a known volume of the gas by the rays was determined.

In order to ionise the gas energy has to be absorbed, and the intensity of the radiation falls off more rapidly than the law of inverse squares. Assuming that the energy of the radiation absorbed in the gas is expended in the production of ions, then, knowing the coefficient of absorption of the rays in the gas, the total current produced by the complete absorption of the whole radiation given out by the bulb into the gas can be deduced.

Let i = maximum current produced by the total ionisation of the gas by the rays,
n = total number of ions produced per sec.,
ϵ = charge on an ion.
Then $i = n\epsilon$.
Let H = heating effect per sec. due to the rays when absorbed in a metal,
E = total energy of the rays in ergs,
Then E = JH, where J = Joule's equivalent.
If W = average energy required to produce an ion, then

$$nW = E = JH,$$
$$\therefore W = \frac{JH}{n} = \frac{JH\epsilon}{i}.$$

The values of H and i are experimentally determined, and, assuming the value of ϵ, namely, $6{\cdot}5 \times 10^{-10}$ electrostatic units, determined by J. J. Thomson, the value of W is found in absolute measure.

Heating Effect of the Rays.

An automatic focus tube was employed, excited by a large induction coil with a special form of Wehnelt interrupter giving 57 breaks per second. The bulb gave out intense rays of a very penetrating character.

The heating effect was measured by determining the variation of resistance in a specially constructed platinum bolometer when the rays fell upon it. The heating effect was standardised by observing the change of resistance caused by the passage of a known current through the bolometer. Special precautions were taken to screen off all heating effects except that due to the X-rays employed.

About ·55 of the incident rays were absorbed in the platinum bolometer. The energy dissipated in exciting secondary radiation at the surface of the platinum was neglected in comparison with the total energy absorbed.

The rate of supply of heat to the bolometer surface (area 92·2 square cms.) at a distance of 26 cms. from the source of the rays was about

0·00014 gramme-calorie per sec.

The total energy of the rays given out from the front surface of the platinum antikathode (omitting absorption of rays in glass of bulb, air, and screens, &c.) was

0·011 gramme-calorie per sec.

Absorption of X-Rays in Gases.

A null method was employed, as the absorption of the rays in air at atmospheric pressure was small. The rays passed through two long brass tubes with aluminium ends, and the current produced by the rays, after passing through one tube, was balanced against the current due to the other. On exhausting one tube the electrometer balance was disturbed. From measurements of the deflection per second from the balance and the deflection per second due to the rays after passing through one tube, the absorption can be calculated. The mean value of the coefficient of absorption of the rays in air at atmospheric pressure was found to be

0·000279,

or the rays would pass through 24·7 metres before absorption reduced the intensity of the radiation to one-half.

The absorption was found to be proportional to the pressure from a half atmosphere to three atmospheres.

The coefficient of absorption in carbonic acid gas was found to be 1·59 times the absorption in air.

Energy required to produce an Ion.

The current produced when a given volume of the gas was ionised by X rays was determined by means of an electrometer. In order to get rid of the secondary radiations set up when X rays strike on a conductor, the rays passed between two charged parallel plates without striking them. A guard-ring method was employed to ensure uniformity of the electric field.

The value of the ionic energy was deduced from the determination of the current, heating effect and absorption of the

rays. The mean value of the energy required to produce an ion in air at atmospheric pressure and temperature was found to be

$$1.90 \times 10^{-10} \text{ ergs}.$$

This value is much greater than the energy required to produce hydrogen and oxygen ions in the decomposition of water.

The ionic energy of air was found to be approximately the same from pressures of one-half to three atmospheres.

The method of determining the ionic energy for other gases is described, and the evidence that the "ionic energy" is the same for all gases is discussed.

Emission of Energy from Radio-active Substances.

The velocity of the ions produced by Röntgen and uranium radiation in air has been shown to be the same. The ions are thus probably the same, and it is a reasonable assumption that the same energy is required in both cases to produce them. On this assumption the energy radiated by the radio-active substances can be determined.

The radio-active material was spread over a known area and the maximum current produced between the parallel plates determined. The number of ions produced, and consequently the energy to produce them, can be calculated.

For a thick layer of uranium oxide (3·6 grammes spread over a surface of 38 cm.) the energy radiated into the gas for 1 sq. cm.) of the surface is

$$10^{-11} \text{ calories per second.}$$

This amount of energy would suffice to raise 1 c.c. of water 1° C. in 3000 years, assuming no loss of heat by radiation. From observations on the current due to a very thin layer of uranium oxide it is shown that the energy radiated into the gas is not less than 0·032 calorie per year for every gramme of the substance.

The energy radiated from thorium and radium is also considered, and the presence of the rays from radium deflected by a magnet is taken into account.

In the case of radium, which is 100,000 times more radio-active than uranium, the emission of energy per gramme of the substance is not less than 3000 calories per year.

Distance between the Charges of the Ions in a Molecule.

On the assumption that the energy absorbed in producing an ion is due to the work done in separating the ions against the forces of their electrical attraction, it can be shown that the mean distance between the charges of the ions in the molecule is

$$1.1 \times 10^{-9} \text{ cm.}$$

This is only 1/30 of the probable diameter of the atom. This result is in accordance with the view recently advanced by J. J. Thomson, that ionisation is produced by the removal of a negative ion from the molecule, and that the negative ion is only a small fraction of the mass of an atom.

Minimum Potential required to produce a Spark.

If the production of ions is necessary before a spark can pass, it can readily be deduced from the value of ionic energy that a spark cannot pass for a potential difference less than 175 volts. Experiments have shown that the minimum value is over 300 volts The theoretical value is of the same order, but from the complexity of the phenomena a very close agreement could not be expected.

Efficiency of a Fluorescent Screen.

Photometric comparisons were made of the light from a fluorescent screen, excited by the X-rays, with the standard Hefner-Alteneck amyl lamp. The energy of the visible radiation from the amyl lamp has been determined in absolute measure by Tumlirz (*Wied. Annal.*, vol. 38, p. 640), and the energy of the rays was measured by the method explained earlier in the paper. From these results the efficiency of the transformation of X-rays into visible light (compared with the amyl lamp) was found to be

4·4 per cent.

A method of determining the intensity of X-rays in absolute measure by photometric observations is explained.

Entomological Society, October 17.—Mr. G. H. Verrall, President, in the chair.—Mr. A. H. Jones exhibited a series of *Pararge maera*, a light form resembling *P. megoera* from the Basses Alpes and the Cévennes; a dark form approaching *P. hiera* from Cortina; and an intermediate form from the Italian Lakes; also a variety of *Lycaena corydon*, female, in which the under wing showed a decided blue coloration, taken at Lago di Loppio near Riva. Dr. Chapman suggested that the union between the three named species of *Pararge* was very near, if the species were not indeed identical.—Mr. A. J. Scollick exhibited a specimen of *Cethosia cyane*, a species inhabiting North-West India, which had been taken this year on the wing near Norwich. It was suggested by Mr. Distant that this was a case of accidental importation, probably in the pupal condition.—Mr. H. Rowland-Brown exhibited specimens of *Erebia glacialis*, taken this year on the Stelvio pass, showing transitional forms to the var. *Alecto*. He said that the typical form and the variety were not found flying together, but on opposite sides of the valley. Dr. Chapman observed that the darker specimens approached to the form of *E. melas* found in the neighbourhood of Cortina-di-Ampezzo. Specimens of *E. glacialis* also exhibited from Saas Fée and Evolena showed marked inferiority in size and brilliancy of colour.—Mr. W. L. Distant exhibited a piece of Hawkesbury sandstone from Australia, showing the borings of Termites, and in connection with the same communicated a note from the *Proceedings* of the Linnean Society of New South Wales (Pt. iii. 1899, p. 418), as follows:—"Mr. D. G. Stead exhibited specimens of Hawkesbury sandstone (1) From the sea-shore between tide marks showing the tunnelling of Marine Isopods (*Sphaeroma*) with the living animals *in situ*; and (2) from the hill-tops overlooking Port Jackson, offering examples of the borings which so often attract notice and the production of which has been attributed to Hymenoptera, and also to the Termites. Since last meeting Mr. Stead reported that he had investigated the matter and that, after breaking up a quantity of stone, he had come upon Termites, of a species at present undetermined, actually at work, specimens of which he exhibited.—Mr. M. Burr exhibited a male and female specimen of *Anisolabis colossea*, Dohrn., from New South Wales—the largest known earwig in the world.

PARIS.

Academy of Sciences, October 29.—M. Maurice Lévy in the chair.—On a method of Riemann and on linear partial differential equations, by M. R. Liouville.—The application of the interference method to the measurement of wave-lengths in the solar spectrum, by MM. A. Perot and Ch. Fabry. The method described permits of the direct comparison of the wave-length of a given dark line in the solar spectrum with a known cadmium ray, a single experiment requiring only the measurement of the diameters of two rings.—On the ammoniacal arsenates of nickel, by M. O. Ducru. Nickel forms three ammoniacal arsenates corresponding to those previously described for cobalt.—On the selenides of cobalt, by M. Fonzes-Diacon. Cobalt combines with selenium giving according to the conditions of the experiment $CoSe_2$, Co_2Se_3, Co_3Se_4, and CoSe. At a high temperature all these selenides are reduced by hydrogen to Co_2Se, which, after prolonged contact with the gas, loses all its selenium.—Modification of the chemical properties of some simple bodies by the addition of very small proportions of foreign substances, by M. Gustave LeBon. Magnesium and aluminium amalgams behave differently, from either of their constituents taken singly, towards water and air.—Cellulose, precipitated cellulose and hydrocellulose, by M. Leo Vignon. The reducing properties, velocity of saccharification, and heats of combustion of cellulose that had been submitted to different modes of treatment were determined. Solutions of strong alkali produced apparently a polymerisation, and similar effects were caused by dilute acids, but none of these celluloses possessed any reducing properties, and thus were sharply differentiated from the oxycelluloses.—On two ketones containing the acetylene grouping, acetyl-œnanthylidene and benzoyl-œnanthylidene. Transformation into β-diketones by hydration, by MM. Ch. Moureu and R. Delange. Amylacetylene $CH_3.(CH_2)_4—C\equiv CH$ is converted into its sodium derivative, and this, suspended in ether and treated with the acid chloride, gives the corresponding ketone. With strong sulphuric acid these ketones are hydrolysed, giving the β-diketones $C_5H_{11}.CO.CH_2.CO.CH_3$ and $C_5H_{11}.CO.CH_2.CO.C_6H_5$.—Transformation of α-amido-acids into phenylhydantoïns, by M. A. Mouneyrat. A description of the preparation and

properties of γ-phenylhydantoin, phenyl-methyl-hydantoin, phenyl-ethyl-hydantoin, phenyl-isobutyl-hydantoin, and phenyl-benzyl-hydantoin.—On the regeneration of a confined volume of air by means of sodium peroxide, by M. George F. Joubert.—On the gaseous exchanges between plants and the atmosphere, by M. Th. Schlœsing, junr. An extension of previous work on the same subject to plants growing in soils containing ammonia salts as the only available source of nitrogen, and free from the nitrifying organism.—A case of rapid transformation of wood into a substance resembling a combustible fossil, by M. G. Arth.—On the examination of contaminated waters for cystine, by M. M. Molinié. The author has repeated the experiments of M. Causse on this subject, and finds that the reagent proposed as a test for cystine gives a permanent orange coloration, not removable by sulphurous acid, even in distilled water. Further examination of the reaction showed that the tint is produced only when the test solution has an acid reaction. The test would thus appear not to be a characteristic one for cystine.—On a new sporozoa from the larvæ of Diptera, by M. Louis Léger.—Precocity and sexual periodicity in man, by M. Gustave Loisel. An attempt to explain the phenomenon of sexual periodicity by the periods in the evolution of spermatogenesis in man and the higher vertebrates.

NEW SOUTH WALES.

Royal Society, August 8.—The President, Prof. Liversidge, F.R S., in the chair.—The President announced that the third science lecture of the Royal Society of New South Wales' series for 1900, viz. a Study of the Mechanics of the Human Frame-work, by Prof. T. P. Anderson Stuart, would be given in the Royal Society's House on August 22.—The following papers were read: Notes on rack railways, by C. O. Burge.—On the damage done to the Seal Rocks lighthouse by lightning on July 10, by C. W. Darley. The author said that the lighthouse tower was fitted with a solid copper lightning conductor extending half round, and was attached at the top to the copper roof of the lantern. The electricity evidently entered the vane on top of the lantern dome, the end being bent and fused, and thence passed down the lightning rod. A portion of the current was communicated to the electric bell wires on the middle floor. These wires led to the principal and assistant light-keepers' quarters, and were laid underground in a 1-inch iron pipe for a distance of 300 feet. The current had tried to make earth at three places, for the pipe was burst and the earth above blown away.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 8.

MATHEMATICAL SOCIETY, at 5.30.—Annual General Meeting.—On the Transmission of Force through a Solid: Lord Kelvin, G.C.V.O.—In a Simple Group of an Odd Composite Order every System of Conjugate Operators or Sub-groups includes more than Fifty: Dr. G. A. Miller.—Prime Functions on a Riemann Surface: Prof. A. C. Dixon. (i) Further Note on Isoscelians; (ii) On Two In-triangles which are similar to the Pedal Triangle: R. Tucker.—(i) A General Congruence Theorem relating to the Bernoullian Function; (ii) On the Residues of Bernoullian Functions for a Prime Modulus, including as Special Cases the Residues of the Eulerian Numbers and the I-numbers: Dr. Glaisher, F.R.S.—On Green's Function for a Circular Disc: H. S. Carslaw.—On the Real Points of Inflexion of a Curve: A. B. Basset, F.R.S.—On Quantitative Substitutional Analysis: A. Young.—On a Class of Plane Curves: J. H. Grace.—On Group Characteristics, and on some Properties of Groups of Odd Order: Prof. Burnside, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Inaugural Address: Prof. J. Perry, F.R.S.

FRIDAY, NOVEMBER 9.

ROYAL ASTRONOMICAL SOCIETY, at 8.—Observations of Nebulæ made at the Chamberlin Observatory, University Park, Colorado: Prof. H. A. Howe.—On the Appearance of Saturn's Crape Ring in 1900: E. M. Antoniadi.—Observations of Jupiter and his Satellites made at Mr. Crossley's Observatory, Bermerside, Halifax, 1899-1900: J. Gledhill.—Photographic Measures of the Ring Nebula in Lyra and of the Neighbouring Faint Stars: F. P. Leavenworth.—(1) Ephemeris for Physical Observations of the Moon for 1901; (2) Note on the Moon's Eclipse Diameter: A. C. D. Crommelin.—The Occultation of Saturn, 1900 September 3: Rev. S. J. Johnson.—Variable Stars in Star Clusters: A. W. Bickerton.—On the Disappearance from Photographic Films of Star Images, and their Recovery by a Chemical Process: Isaac Roberts.—Note on the Total Eclipse of the Sun, 1900 May 28, observed at Algiers: Rev. C. D. P. Davies.—Micrometric Measures of the Diameter of Neptune and Satellite made with the 28-inch Refractor: Royal Observatory, Greenwich.—*Probable Papers*: Stationary Meteor Radiants: an Alternative Explanation: H. H. Turner.—Photographic Observations of the Planet Eros: a Close Approach to a Small Star: F. A. Bellamy.—On the Variable Velocity of α Persei: H. F. Newall.—On the System of ζ Herculis as deduced from Micrometric Measures and Meridian Observations: T. Lewis.—Kinematograph Photographs of the Total Solar Eclipse of 1900 May 28: Nevil Maskelyne.

PHYSICAL SOCIETY, at 5.—Electromotive Force and Osmotic Pressure: Dr. R. A. Lehfeldt.—On Astigmatic Lenses: R. J. Sowter.—(*a*) On a Phase-turning Apparatus for use with Electrostatic Voltmeters; (*b*) On a Method of Measuring Power in Alternate-Current Circuits; (*c*) Note on obtaining Alternating Currents and Voltages in the same Phase for Fictitious Loads: A. Campbell.—On the Refraction of Sound by Wind: Dr. E. H. Barton.

MALACOLOGICAL SOCIETY, at 8.—Morphological and Descriptive Notes on the Genus *Cryptoplax*: H. A. Pilsbry.—Notes on a Remarkable Nudibranch from N.W. America: Sir Charles Eliot.—On the Anatomy of some Agnathous Molluscs from New Zealand: R. Murdoch.—Fate of the Type Specimen of *Voluta Roadknightae*, McCoy: W. Baldwin Spencer.

MONDAY, NOVEMBER 12.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Introductory Address: The President.—Expedition through Somaliland and between Lake Rudolf and the Nile: Dr. A. Donaldson Smith.

TUESDAY, NOVEMBER 13.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Metropolitan Terminus of the Great Central Railway: George A. Hobson and E. Wragge.

MINERALOGICAL SOCIETY, at 8.—Anniversary Meeting.—An Improved Form of Three-Circle Goniometer: G. F. H. Smith.—A Simple Proof of the Rationality of the Anharmonic Ratio of Four Faces of a Zone: Harold Hilton.—Sulpharsenites of Lead from the Binnenthal. Part II. Rathite: R. H. Solly.

THURSDAY, NOVEMBER 15.

ROYAL SOCIETY, at 4.30.—The following Papers will *probably* be read: Further Note on the Spectrum of Silicium: Sir Norman Lockyer, F.R.S.—On Solar Changes of Temperature and Variations in Rainfall in the Region Surrounding the Indian Ocean: Sir Norman Lockyer, F.R.S., and Dr. W. J. S. Lockyer.—Argon and its Companions: Prof. W. Ramsay, F.R.S.—Data for the Problem of Evolution in Man. VI. A First Study of the Correlation of the Human Skull: Dr. Alice Lee and Prof. K. Pearson, F.R.S.—Mathematical Contributions to the Theory of Evolution. IX. On the Principle of Homotyposis and its Relation to Heredity, to the Variability of the Individual and to that of the Race. Part I. Homotyposis in the Vegetable Kingdom: Prof. K. Pearson, F.R.S.—On Retinal "Blaze" Currents: Dr. Waller, F.R.S.

LINNEAN SOCIETY, at 8.—Contributions to the Comparative Anatomy of the Cycadaceæ: W. C. Worsdell.—On a New Parasitic Copepod: Miss Alice L. Embleton.

CHEMICAL SOCIETY, at 8.—The Bases contained in Scottish Shale Oil: F. C. Garrett and Dr. J. A. Smythe.

FRIDAY, NOVEMBER 16.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Capacity of Railway Waggons as affecting Cost of Transport: D. Twinberrow.

FOSSIL PLANTS AND EVOLUTION.

Studies in Fossil Botany. By D. H. Scott, F.R.S. Pp. xiii + 533. (London: Adam and Charles Black, 1900.)

THE present work owes its origin to a course of lectures delivered at University College in 1896. In appealing to a wider audience, Dr. Scott has rendered an important service to biological science, and has placed before the botanical student some of the most striking results of palæobotanical investigation, which cannot fail to demonstrate, even to the most sceptical, the supreme value of fossil records from the evolutionary standpoint. The author expressly states in the preface that his object has by no means been to write a manual of fossil botany,

"but to present to the botanical reader those results of palæontological inquiry which appear to be of fundamental importance from the botanist's point of view."

The study of petrified fragments of Palæozoic plants has of late years contributed more trustworthy and important data towards the solution of phylogenetic problems than any other department of palæobotany. It is, however, most desirable that the student should recognise that the range of fossil botany is wide, and that results of primary importance may be reasonably expected also from investigations along other lines than those which are followed in the present work.

A word of praise is due to Mr. Gwilliam, who has drawn the majority of the admirable illustrations. After a brief introduction, the author proceeds to deal with the most important Palæozoic representatives of the Equisetales, Sphenophyllales, Lycopodiales, Ferns, Cycadofilices and Cordaiteæ; a short account is given also of Mesozoic Gymnosperms. The concluding lecture, in which the general results are summarised in a clear and convincing style, is of special interest as one of the most striking contributions towards the scientific construction of botanical genealogies that we have ever read. In the lectures on the Equisetales we have a concise account of the extinct ancestors of the modern Horsetails, more particularly of the somewhat comprehensive genus *Calamites* and of the various types of fructification included in the Calamarieæ. Lecture iv. treats of the extinct group Sphenophyllales, including *Sphenophyllum* and *Cheirostrobus*; the latter genus, originally described by its author—Dr. Scott—in 1897, is of primary importance as enabling us to connect together such apparently distinct phyla as the Equisetales, Lycopodiales and Sphenophyllales. Three lectures are devoted to the Lycopodiales. Satisfactory restorations of extinct plants are always a difficulty; that of *Lepidodendron elegans* hardly does justice to what must have been one of the most striking and beautiful trees in the forests of the Palæozoic era. Although our knowledge of the anatomy of *Lepidodendron* is in several respects fairly complete, there are still a few points on which further information is much to be desired.

Dr. Scott suggests "a certain similarity" to *Isoetes* as regards the manner of secondary growth in a Lepidodendroid stem, and refers to "considerable difficulties" presented by the phloem of the Lepidodendreæ, without dealing with these questions at length. We are, I believe, still in want of satisfactory evidence of the existence of typical phloem, which was added to by cambial activity, at least in the case of the vegetative shoots of the Lepidodendreæ. The account of the leaves of *Lepidodendron* is particularly interesting; the stomatal grooves on the lower surface of the leaf suggest a xerophytic adaptation. Indications of xerophytism are afforded by other anatomical characters in certain Palæozoic types, and we are tempted to express the wish that a lecture had been devoted to the consideration of such evidence as is available bearing on the physiology and biology of Palæozoic plants. The nature of the large scars on the well-known Ulodendroid branches is admittedly still unaccounted for; it would have been a satisfaction to have a new and carefully made drawing of the often quoted specimen, described by Mr. D'Arcy Thompson in 1880, which is considered by many to prove that the scars are the result of the mutual pressure between the bases of cones and the stems which bore them.

One of the most striking cones included in the account of various Lepidostrobi is an excellent heterosporous type, which was in all probability borne on the well-known stems known as *Lepidodendron Veltheimianum*.

In referring to the enormous output of spores necessitated by the arboreal habit of the Lepidodendreæ, an allusion is made to an exceedingly important discovery, which has not yet been published in full, of a Lepidodendroid strobilus possessing seeds. This new *Cardiocarpon*-bearing cone, which Dr. Scott has recently investigated, is of great interest, as showing that "some of the Palæozoic Lycopodiales actually crossed the frontier line which separates Sporophyta from Spermaphyta." This discovery naturally suggests an additional argument in favour of a possible connection between the Lycopodiales and Coniferæ; but, on the other hand, as we are reminded in the concluding lecture, there are difficulties in the way of connecting the Coniferæ with the Lycopods, and arguments are not wanting in favour of the view that the Gymnosperms as a whole may have had a common origin from the Filicales.

The differences between *Sigillaria* and *Lepidodendron* and the exact morphological nature of *Stigmaria* are, as the author notices, points on which further light is needed. Recent research has added enormously to our exact knowledge of numerous extinct types which were until lately unknown; it has also taught us that we have still much to learn with regard to some of the commonest fossils from the Coal-measures.

A photograph is given (p. 207) of a transverse section of a Sigillarian stem, which was briefly described some years ago by Mr. Carruthers, but it is to be regretted that no account of the anatomy of this stem has ever been published. It is unfortunately very rare to find an undoubted *Sigillaria* in which the tissues are preserved, and we would express the hope that the example referred to in Lecture vii. may not remain much longer undescribed.

In the lectures on ferns, the most important new facts are those relating to the Botryopterideæ, which are now shown to afford among the Filices a striking instance of the combination of affinities in one extinct family. The account of this family is particularly interesting.

Dr. Scott's critical and thorough investigations have

played a prominent part in supplying us with trustworthy guides, which afford the means of tracing to their common origin many divergent lines of plant-evolution. Among other genera which have thrown new light on the course of evolution, the two Cycadofilicinean types *Heterangium* and *Lyginodendron*, dealt with in Lectures x. and xi., may be specially mentioned.

It is impossible in a short review to deal adequately with all the subjects of the lectures. A few remarks might be made by way of criticism bearing on nomenclature and terminology, but this is a matter of secondary importance. The work, as a whole, has been admirably done; its value is considerably enhanced by the fact that many of the conclusions are founded on the author's personal investigations which are characterised by ability, thoroughness and sound judgment. It may be safely said that there is no source from which the botanist can gain so clear a view of the far-reaching importance of researches into the morphology of Palæozoic plants than from the volume before us. A. C. S.

PHYSICAL CHEMISTRY IN AMERICA.

The Journal of Physical Chemistry. Edited by Wilder D. Bancroft and Joseph E. Trevor. (Cornell University, Ithaca, New York.)

THE recent development of physical chemistry may be said to date from the year 1887. The fundamental ideas on which the modern superstructure rests had been conceived and even published before that time; but though the phase rule of Gibbs, the osmotic pressure theory of van 't Hoff and the electrolytic dissociation theory of Arrhenius had all appeared in print, they were buried in the little-known transactions of minor academies, and so escaped general notice. It is undoubtedly to Ostwald that the popularisation of physical chemistry is due. Himself an unflagging worker in the field, he gathered together and systematised the work done by his predecessors in the *Lehrbuch der allgemeinen Chemie*, which was completed in 1886. In 1887 the new era began with the establishment of his *Zeitschrift für physikalische Chemie.* To the first volume of this journal, van 't Hoff and Arrhenius contributed succinct accounts of those theories which have since so largely inspired and dominated physicochemical work. The extent of this work may be gathered from the fact that of the *Zeitschrift* thirty-four volumes have now been published, each volume containing on the average nearly 750 pages.

Amongst the students frequenting Ostwald's laboratory in Leipzig there has always been a large number of Americans, eager and energetic after their kind. Most were enthusiastic for the new theories, and in the best the enthusiasm was tempered by intelligent and judicious criticism, differing widely from the suspicious conservatism so often displayed in this country when these theories have been under discussion. To this happy scientific temperament we owe the fact that to-day physical chemistry is being much more thoroughly cultivated on the other side of the Atlantic than in Britain. In many, perhaps most, of the Universities it is taught as part of the student's ordinary chemical equipment, and the student who wishes to specialise in the subject can find in Boston or at Cornell ample opportunity and encouragement for study and research.

Cornell University has published since 1897 the *Journal of Physical Chemistry* under the editorship of two of its professors. On the cover of the *Journal* for March 1899 we find that the department of chemistry offers the following courses, each of which runs through the entire year.

(1) *The Phase Rule.*—A comprehensive qualitative treatment of all types of chemical equilibrium, as these are classified by the Phase Rule of Gibbs.

(2) *The Law of Mass Action.*—Non-mathematical exposition.

(3) *Mathematical Chemistry*, I.—The mathematical theories of chemical equilibrium, of the velocities of reactions, and of electrochemistry.

(4) *Mathematical Chemistry*, II.—A systematic study of Duhem's "Traité élémentaire de Mécanique chimique."

(5) *The History of Thermodynamics.*—Especial consideration is given to the physicochemical applications of thermodynamic theory.

(6) *Introduction to Mathematical Chemistry.*—An elementary exposition of the essential features of: (*a*) the theory of surfaces, as applied in geometric representations of the thermodynamic properties of bodies; (*b*) spherical harmonics, as applied in the theory of diffusion; (*c*) the principles of least and varying action, as applied to the problems of chemical and electrochemical equilibrium.

(7) *Electrochemistry.*—Historical treatment.

(8) *The Velocities of Reactions.*—Historical account and mathematical theory.

(9) *Laboratory Work.*—Laboratory methods and experimental research.

Two or three lectures weekly are given in each course, the aggregate weekly number of lectures being twenty. Certainly no German university offers a more complete or systematic course of instruction in physical chemistry than this.

As might be expected from the countrymen of Gibbs, the lecturers give a prominent place to the application of thermodynamics to the problems of chemical equilibrium. The same predilection appears in the *Journal*, to which Duhem, the chief contemporary exponent of the subject, is a frequent contributor. Electromotive force also receives a large share of attention. The reviews of books and critical abstracts of papers on physical chemistry appearing in other publications are in general well done, being brief, clear and to the point.

The personality of one of the editors is deeply impressed on the *Journal.* His views of the physical chemistry of to-day may perhaps best be seen from the following extract, taken from a notice of the new edition of Ostwald's *Grundriss der allgemeinen Chemie*:—

"Physical chemistry is not yet a quantitative science: it is a pseudo-quantitative science. There are all the outward signs of a quantitative science. We have formulas and tables; we make use of thermodynamics and the differential calculus; but this is for the most part a vain show. Long before we reach the point where the formula is to be tested experimentally, we slip in a 'simplifying assumption'; that the concentration of one component may be considered as constant; that the heat of dilution is zero; that the solute may be treated in all

cases as though it were an indifferent gas; that the concentration of the dissociated portion of a salt may be substituted for the total concentration; &c., &c. The result is that our calculations apply at best only to limiting or ideal cases, where an error in deducing the formula may be masked by the error of observation. Helmholtz did not do this, but Helmholtz is considered old-fashioned."

What Mr. Bancroft would have us do is to study concentrated solutions. The object is most laudable; but until a Helmholtz appears who is capable of attacking the problem in all its complexity, physical chemists will probably continue their work on dilute solutions, for which the conditions are comparatively simple, and the behaviour of which is represented closely by the results deduced from a consideration of the limiting or ideal cases above referred to.

There is one point about many of the reviews (and some of the original contributions) which calls for remark—they seem needlessly scathing. Should any one be so unfortunate as to differ in opinion from the reviewer, he is forthwith tomahawked, and his scalp brandished in triumph before the horrified reader. It is painful to see one's friends—nay, even one's enemies—ruthlessly butchered in this fashion, and we would earnestly counsel a less close adherence to the former methods of the Wild West. J. W.

THE EXPLORATION OF THE UPPER AIR.

Sounding the Ocean of Air. Being six lectures delivered before the Lowell Institute of Boston in December, 1898. By A. Lawrence Rotch, S.B., A.M. "Romance of Science" Series. Pp. viii + 184. (London: Society for Promoting Christian Knowledge, 1900.)

A CORDIAL welcome for this little book may be anticipated from the fact that it is the latest addition to the series which has given us Boys's "Soap Bubbles," Perry's "Spinning Tops," Worthington's "Splash of a Drop" and Sir R. Ball's "Time and Tide." Its author has won for himself a prominent place among those who are best acquainted with modern ways of sounding the ocean of air, by the work done at his observatory at Blue Hill, Massachusetts, and by his personal association with the observers of clouds and the users of balloons and kites in Europe.

Perhaps the very width and depth of his acquaintance with the details of the subject have made the task of the popular exposition of it in six short chapters a difficult one. The procession of facts, each one of great interest in itself, is apt to become panoramic and even kaleidoscopic; and when one page, or sometimes one paragraph, has to accommodate a succession of scientific ideas, the inexpert reader may find himself a little bewildered with the rapidity of the transitions, and occasionally even with some short cuts to scientific conclusions.

After a short historical introduction the book deals successively with the exploration of the upper air by means of clouds, balloons and kites. Each section gives a brief account of the earlier experiments, before treating of the recent results. The romance begins in the first chapter with a striking diagram of the heights of certain observatories, mountain peaks, kites and balloons, showing one balloon—an unmanned one, be it said—at the almost incredible height of 13 miles or more (upwards of 70,000 feet), where the corresponding barometric pressure is about one and a half inch of mercury; it culminates in the chapter describing these extremely lofty ascents. The chapters on the various types of balloon, captive balloons, free balloons and *ballons sondes* (unmanned balloons) are, both from the historic and the scientific point of view, the most interesting to the general reader. The study of clouds is clearly too large a subject for a single chapter; and the final chapters, which are devoted to the description of kites and the results obtained at Blue Hill, enter into details which the meteorologist will find of great value and interest, but which require close attention from the reader. The diagrams with which the book is illustrated have suffered a little from the reduction in scale for the purpose of reproduction; but the reader who will take the trouble to follow them carefully with the text will be rewarded by obtaining an excellent survey of the work done with kites up to a height of 12,000 feet, and some idea as to what they may be expected to accomplish in the future.

One side of the romance of kite work is only touched with a light hand. The Berlin experimenters could supply at least one thrilling story of a kite that absconded for the night with its wire, and made a long and very eventful journey; but Blue Hill has perhaps been more fortunate; doubtless its situation lends itself less easily to romantic exploits of that description.

It is interesting to notice the geographical distribution of the work of exploring the upper air as it appears in Mr. Rotch's account. Speaking quite generally, the United States are conspicuous for the work with kites, Germany for various forms of manned balloons, and France for *ballons sondes*, although the most adventurous of these last, the "Cirrus," belonged also to Berlin; while cloud work is more evenly distributed, the services of Hildebrandsson in that department render Sweden conspicuous. Great Britain is credited with an active share in the initiation or early development of the scientific exploration of the air by clouds, balloons and kites in turn, but in later years seems to have withdrawn from such enterprises.

Mr. Rotch's interesting lectures may well leave the impression that the further sounding of the upper air of the British Isles might be exciting on account of the special situation and circumstances of the islands, but, for the same reason, would be of great scientific importance.

OUR BOOK SHELF.

The Locust Plague and its Suppression. By Æneas Munro, M.D., Edinb. and Cordova, Fellow of the Faculty of Physicians and Surgeons of Glasgow. With illustrations. Pp. xvi + 365. (London: Murray, 1900.)

THE volume before us has been prepared by the author after nearly ten years' observation of locust ravages in the Argentine Republic and in South Africa. He is profoundly convinced of the enormous damage caused by locusts in various parts of the world, and has brought together a considerable amount of information respecting the various means which have been adopted for destroying them. Dr. Munro writes from a practical point of view,

and treats the locusts of different countries as, to all intents and purposes, the same insect. His book will no doubt be very useful to agriculturists in countries infested by locusts; but he scarcely allows for the variations in habit which exists between different species. For instance, he observes that the South American locusts are said to breed on the shores of certain lakes in Bolivia, and asserts that if they could be destroyed in this locality they would be exterminated from the whole of South America (!). It is hardly possible to take such a remark seriously; but we may perhaps observe that even if the story were true, it could only be true of one or two species at most. It is also suggested that ophthalmia in Egypt (well known to be spread by flies) may be caused by locusts.

Dr. Munro also claims that his book is the first on the subject; but we are more inclined to think that a locust bibliography would fill a book as large as his own. Besides, some of his illustrations appear to be taken from American works.

An interesting account is given of the appearance of what is called the "new" locust in South Africa, and he quotes from Mr. Péringuey: "The present species was very closely allied to *Acridium peregrinum*, and in the same way that that species had swarmed into Algeria after the myriads of a smaller locust, *Stauronotus* (not *Jauronotus*, as printed) *marocanus*, had been destroyed at great expense, this present species was following in the rear of a smaller locust, *Pachytylus migratorius*" (§ 166). One curious point is that the "new locust" is said to be unwholesome, if not actually poisonous, by the natives. However, in § 32, under the heading, "Scientific Definition," we read, "the locust we have here (in Africa) is, to all intents and purposes, the same insect called technically the *Acridium peregrinum*, *Locusta migratoria*, or the wandering locust" (Fig. 4*a*, p. 37). Here it will be seen that two species, by no means closely related, are spoken of as if they were the same; and on turning to p. 37 we find two figures of locusts, specified as "The African Locust" and "The South American Locust," as if there was only one species in each continent.

The book is very diffusely written, and treats of a great variety of subjects, some of them rather irrelevant to the locust question. It is, however, divided into 900 numbered paragraphs, and provided with an excellent index, which will make it a useful book of reference, though it would be rather a formidable undertaking to read it through from cover to cover.

Leçons d'Anthropologie Philosophique, ses Applications à la Morale Positive. Par D. Folkmar. Pp. xiv + 336. (Paris: Schleicher Frères, 1900.)

SCIENCE exists for the sake of something beyond itself. Doing, not knowing, is what determines the place and significance of any body of doctrine in the hierarchy of arts and sciences. The synthesis of the human sciences in the light of their worth for action is not effected by sociology. This fails to include certain individual sciences. In this way Prof. Folkmar makes the transition from the sociological studies, which engrossed him at Chicago, to the philosophical, as opposed to physical, anthropology, which he expounds from his chair at Brussels.

The changed point of view involves an endeavour after a new classification of the sciences of man, a critical determination of the limits of those sciences as hitherto pursued, and a sketch of the unifying conceptions that involves disquisitions psychological, anthropological in the narrower sense, and ethical. To the practical applications of his teaching Prof. Folkmar proposes to devote his life.

Dr. Folkmar may be described as Spencerian, though critically so. He rests much on Letourneau, and has studied in the following of Giddings, Lester Ward and other of the "new sociologists." He owes something to Guyau. He exhibits on the whole a sober judgment, and is frequently suggestive in his treatment even of well-worn topics. It is therefore the more to be regretted that he has almost buried good work among platitudes, second-hand matter and pretentious technical phraseology, doubtfully permissible in his *conférences* and inadmissible in the *litera scripta* meant to endure.

Terms such as *anthropographie* (of which different misprints occur, pp. 71, 72), *archéographie* (which means ancient geography), and *praxéologie* detract from the merit of Dr. Folkmar's graphic representation, upon the faces of a cube, of the sciences of man. His much use of the word "innervation," defined as meaning simply "a form of vibration of the nervous tissues," is a weakness of the same kind. Nothing, surely, is gained by declaring the question of the unitary origin of the race to be "on ultimate analysis the question of monogenism *versus* polygenism" (p. 127).

More serious in a work of scientific pretensions is what we take to be a missing of the main point with regard to polyandry in the remark (p. 188) that where it obtains many women must needs remain unmarried. That completeness of life can be determined with mathematical exactness (p. 319) needs proof. In an otherwise ingenious suggestion for a grading of scientific asseveration "impossible" (p. 67, line 24) *is* impossible, and "improbable," which is not improbably the right reading, will not balance the "probable" which has preceded.

In fine, though Dr. Folkmar's ability to supply a text-book of anthropology as he conceives it will not admit of question, and an essay from his pen developing, say, the conception which he would substitute for Mr. Spencer's ethical ideal might prove instructive, his present book suggests the high-class amateur who enters for the first time in a tournament of masters.

H. W. B.

The Principles, Construction and Application of Pumping Machinery. By Henry Davey. Pp. xvi + 295; 250 illustrations. (London: Charles Griffin and Co., Ltd., 1900.)

THE purpose of this book, as stated by the author, is to present information on pumps and pumping machinery in such a form as to make it useful to the practical engineer engaged in the application of pumping machinery in mines and for waterworks, or in other positions where large quantities of water have to be dealt with. This purpose has been fairly accomplished. The information given is of a thoroughly practical character and made plain by numerous illustrations, and the book cannot fail to be of great use either to the student seeking information or to the practical engineer engaged in works requiring pumping machinery.

The first chapter contains an interesting summary of the gradual development of pumping machinery. Cornwall may be said to be the land of the birth of large pumping installations. It was here that both Savery and Newcomen brought into use the power of steam for raising water from the mines, and their engines remained in use until Watt introduced the system of a separate condenser. It is not much more than a century and a quarter ago that Boulton and Watt commenced the manufacture of their engines for the coal-mines in Staffordshire and Warwickshire, but it was Cornwall that afforded the great field for the development of Watt's inventions. The progress of this development is interesting. The coal-mines were becoming deeper and very costly to drain. The proprietors were unwilling to incur the expense of removing the old atmospheric engines put down by Newcomen; and to meet this difficulty Boulton and Watt erected many engines at their own expense, taking as payment one-third of the

saving effected in raising the coal. At one mine where three of Watt's engines were erected the proprietors engaged to pay 800*l.* a year for each engine as a compromise for the third part of the saving in coal.

It was with the Cornish engine that the principles governing steam engine economy were first grappled with; and with the engines used for all purposes on land, pumping engines, even at the present day, are worked with the greatest economy of fuel, examples being given where the engines are worked with an expenditure of less than 2 lbs. per I.H.P. It is interesting to note the change of pressure at which steam is worked now, reaching to 150 lbs. on the square inch, as compared with the 5 lbs. used in many of the old Boulton and Watt engines. These engines were not confined to pumping water from mines, but were applied to reclamation purposes, many of the Boulton and Watt engines, made a century ago, being still in use in the fens of Lincolnshire and Cambridgeshire. These machines were noted for their massive construction and the excellency of the workmanship, as attested by the number of years during which they have done good service.

The other fourteen chapters into which the book is divided deal with descriptions of the various types of pumping engines in use; pumps and pump valves; pit work; shaft-sinking; hydraulic transmission of power in mines; valve gears; waterworks engines; trials of pumping engines; centrifugal and low lift pumps, with descriptions of some of the scoop wheels in use in Holland; hydraulic rams and pumping mains.

Elements of Hydrostatics. By S. L. Loney, M.A. Pp. viii + 248 + xii. (Cambridge: University Press, 1900.)

"ELEMENTS OF HYDROSTATICS" is a subject the limits of which are sufficiently well known to require little definition. In the present instance it includes a fairly complete treatment of centres of pressure of rectilinear areas and circles by what used to be called, at Cambridge, "three-day methods"—also sections on rotating liquids and on tensions of vessels and curves of buoyancy. The book will do admirably for the ordinary run of students preparing for examinations in this subject, and the copious problems and examples should commend it to science students; but there are one or two points in which improvement is desirable. "Whole pressure" has been too long a fetish of the third-rate schoolmaster, who "thinks he is wise when he is not." But instead of banishing this misleading idea to a few lines of small print (or, better, omitting it altogether), and replacing the term "whole pressure" elsewhere by "*resultant thrust* on a *plane* area," Prof. Loney makes confusion worse confounded by speaking, so far as we can make out, indiscriminately of "whole pressure," "whole pressure or thrust" and "whole thrust." Again, there is no reason why we should be left in the dark as to the precise distinction between a perfect fluid and an ordinary fluid, or the reason why the principles of hydrostatics apply with sufficient approximation to the latter; these points are hinted at, but might with advantage be stated more explicitly. The usual figure of the air-condenser, with its valves hanging in an impossible position, is once more reproduced.

There are, to our knowledge, many highly successful teachers who, in their ignorance, persist in their preference for misleading methods of dealing with such notions as "whole pressure," the "parallelogram of velocities," the "binomial theorem" and the like. There are few writers better qualified to prove that scientific accuracy is not incompatible with a successful text-book than Prof. Loney, whose name alone is sufficient to ensure a large circulation for his works. Why, too, does not the Cambridge University Press rise superior to pandering to the fancy of those mathematical masters who know no better?

Minéralogie Agricole. By F. Houdaille. Pp. 299, avec 107 figures dans le texte. (Paris: Félix Alcan, 1900.)

THE object of this little work is to provide agriculturists and others with a knowledge of the properties, physical and chemical, of the minerals important to man, either as constituents of rocks and soils, as fertilisers or as sources of materials used in the arts. The author assumes ignorance of physics, chemistry and crystallography on the part of the reader, and as the descriptive portion of the book would be unintelligible without some knowledge of these subjects, he attempts to give the necessary smattering in an introduction of eighty-nine pages. The laws of crystallography and modern views of crystal structure are dealt with in forty pages, illustrated by a number of indifferent figures, some of which, notably the rhombohedron of Fig. 8, entirely fail to produce on the eye the effect which the author presumably intended. In the chemical section the old equivalent notation is preferred to that usually accepted at the present day; thus, sodium carbonate receives the formula NaO,CO_2+10HO! A considerable portion of the space devoted to analysis is occupied by a picture of an elegant gentleman puffing languidly with a blow-pipe at a long candle fixed in an equally tall candlestick. The rest of the book contains a selection of facts about minerals which can be found in any treatise on descriptive mineralogy, together with some useful information as to methods of determining the permeability of soils and the percentage of calcium carbonate contained in them. We fear, however, that the work will hardly be found readable by any one who has not already had an extensive training in chemistry and mineralogy. It is therefore unlikely to be of much value to the class for whom it appears to be intended, nor can it be recommended to the serious student.

Engine-Room Practice. A Handbook for the Royal Navy and Mercantile Marine. By John G. Liversedge, R.N. Pp. xi. + 292. (London: Griffin and Co., Ltd., 1899.)

MR. LIVERSEDGE'S handbook will be found by all engineers to be a very useful supplement to the more technical treatises of Mr. Seaton and of Messrs. Sennet and Oram. It lays down the whole duty of a marine engineer, and more particularly of a naval engineer, from the day when he receives notice of his appointment; and it is throughout well-written, full, and admirably to the point. The running of the main engines and the care of the boilers are, of course, the chief concerns of the book; but the auxiliary machinery is also well looked after, and there are separate chapters on the electric light, the hydraulic, the refrigerating and the air-compressing plants. The chapter on adjustments and repairs seems to us of especial value, for while a successful repair at sea is often the outcome of what seems an inspiration, its success may at any time be assured by a knowledge of what has been done in similar cases.

We could wish, especially in the present season of divergent opinion on the matter, that the water-tube boiler had received somewhat greater attention. A few pages at the end of the book are specially contributed by Fleet Engineer Edwards, of H.M.S. *Powerful*, and perhaps it were unwise to do more until fuller experience has been gained; but we may expect to see the matter thoroughly taken up in later editions, for no unprejudiced observer can doubt that the water-tube boiler, in one form or another, has come to stay.

While Mr. Liversedge's book is primarily a professional handbook, it will be found, at the same time, to interest all who have any acquaintance with the engineering side of naval life, even though they may have but a superficial knowledge of the ordinary equipment of a ship's engine-room.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Markings of Antilocapra.

IN NATURE of Oct. 11 (p. 586) Mr. R. J. Pocock says: "If the American prong-buck were an inhabitant of Africa, I presume that its conspicuous patterns . . . would be cited as evidence supporting the theory of recognition marks. But in the prairies of the United States there are no species that resemble it in size and form, so as to create confusion as to identity."

The prong-buck is so cited by Wallace ("Darwinism," p. 218), and a figure is given (p. 219) of a similarly-marked gazelle in support of the same theory. But the point of the whole matter rests on the aid given to the members of a herd in following one another, and has nothing whatever to do with the presence of allied species. I cannot understand how Mr. Pocock, who appears to have read Wallace's work, can have overlooked the point of the argument so completely. I have had the pleasure of seeing herds of prong-bucks (*Antilocapra*) in their native wilds (Pecos Valley, and near the Sacramento Mountains, New Mexico), and can readily understand how useful the markings must be in helping the animals to keep together in the dusk or dark, whereas it is not at all probable that they expect to escape observation on the open prairie by daylight. If these animals lived singly, there might be some plausibility in "Thayer's principle," as applied to them, but in herds they can be seen from afar off, and the same must be true of the African gazelles. Their safety is in flight, not inconspicuousness, and the necessity for keeping together when in flight is obvious.

The coyote or prairie-wolf (*Canis latrans* and allies), which also lives on the prairies and is gregarious, has the habit of barking incessantly at night, and this doubtless serves the same purpose as the markings of the prong-buck.

It might conduce to clearness if we divided what are now called recognition-marks into two categories, thus:—

(1) *Recognition-marks*, which assist members of a species in distinguishing their fellows from other species.

(2) *Guide-marks*, which assist members of a species in following one another. The markings of the prong-buck would then come under the head of guide-marks. T. D. A. COCKERELL.

East Las Vegas, New Mexico, U.S.A. October 30.

Curves without Double Points.

MR. BASSET'S objection to the term "non-singular" (see NATURE, Oct. 11, p. 572), arises from a misunderstanding. The ordinary use of the term by English-speaking mathematicians is natural and legitimate; it is applied to curves without double points when the curve in question is defined by a relation among the coordinates of its points. In the case of a curve defined in another manner, for instance by a tangential equation, "non-singular" could not possibly be used in the sense. In fact, the phrase which Mr. Basset denounces as "exceedingly infelicitous and misleading" is one which, standing by itself as Mr. Basset quotes it, strikes a geometrician as unfamiliar; "non-singular cubic curve," "non-singular curve of the nth order," are familiar to him, and are unobjectionable.

In the study of algebraic curves the word *node* is in common use to denote any double point; if it is necessary to distinguish the three chief kinds of double points, the words crunode, acnode, cusp are recognised; and, although the two first are not wholly satisfactory, yet their meaning is unmistakable. Further, we have adjectives nodal, crunodal, cuspidal, binodal, etc. If Mr. Basset's mode of investigation is such that the introduction of new technical terms is really unavoidable, may I suggest that the phrase *nodeless curve* concisely describes a curve without double points? HERBERT RICHMOND.

King's College, Cambridge, November 10.

Euclid i. 32 Corr.

HAMBLIN SMITH writes, these "corollaries were first given in Simson's edition of 'Euclid'" (edition 1872, &c.). J. Walmsley, "Introduction to Geometry" (1880, &c.), styles them Simson's corollaries. Hall and Stevens say these "theorems were added as corollaries to Prop. 32 by Robert Simson" (1888, &c.), and finally, Loney, in his edition of Todhunter's "Euclid," writes, "the corollaries were added by Simson." Many years ago it was pointed out to me that these corollaries, with many interesting applications, were given by Clavius in his edition of the Elements (1607), see pp. 105–108. On p. 107, he cites "ex Campano, si pentagoni singula latera producantur in partem utramque, ita ut quælibet duo extra pentagonum coeant, efficientur quinque anguli ex lateribus coeuntibus æquales duobus solum rectis." Clavius probably is not the first publisher of these results. R. TUCKER.

November 5.

Late Appearance of a Humming-bird Moth.

IN a garden in Lower Addiscombe Road (well in the town of Croydon), I saw a humming-bird hawk-moth to-day sporting over a bed of scarlet geraniums. It was as fresh as if newly emerged. This is the first time I have seen the insect so late in the year. Would it not have been called a "late appearance" even a month ago? It testifies strongly to the unusually open autumn here. J. EDMUND CLARK.

Lile Garth, Ashburton Road, Croydon, November 3.

SOME RECENT ADVANCES IN ZOOLOGY.

TO take stock from time to time of the progress made in its different branches is advantageous in the case of every science, but in none more so than in zoology, where specialisation is now carried to such an extent that the workers in one section have in general but little acquaintance with what their brethren are doing in another. This same subdivision of work renders it, however, extremely difficult for any single writer to give any adequate account of what has been effected during the last year or two in all the different branches of the science, the difficulty being enhanced by the circumstance that the one for 1898 is the latest volume of the "Zoological Record" that has at present been published. All that can therefore be attempted in the present article is to give a fairly full *résumé* of the more notable advances in the branches of zoology with which the writer is best acquainted, and to make mention of such discoveries in other sections of the subject as may have come under his notice.

Among the Mammalia, by far the most important discovery made of late years is the identification by Mr. J. P. Hill, of Sydney, of the existence of a rudimentary placenta in the Bandicoots (Perameles). From this it has been inferred that all Marsupials originally developed a placenta, which has become abortive in the more specialised members of the group. This discovery entails, almost of necessity, a modification in the generally accepted classification of the Mammalia. And instead of dividing the class into the three equivalent groups, Eutheria, Metatheria and Prototheria, Prof. H. F. Osborn has suggested that we should now take only the two divisions of Eutheria and Prototheria; the former being subdivided into Placentals and Marsupials, and the latter (as heretofore) including the Monotremes alone. Placentals and Marsupials may indeed be now regarded as divergent branches of a single stem; the latter being less primitive than are the Insectivora. On the other hand, Monotremes are so different from Eutherians that some zoologists even go so far as to consider them derived independently from Reptiles or Amphibians. In this connection, as tending to emphasise the intimate relationship between Marsupials and the primitive Carnivora, reference may be made to a paper by the present writer (*P.Z.S.*, 1899), in which it is attempted to show that both have a similar dental formula. It may be added that our knowledge of the anatomy of the Monotremes has been largely increased by the publication of the results of the work on the specimens collected by Dr. Semon, now in course of publication in the *Jenaische Zeitschrift*. Moreover, much interest

attaches to the account recently given by Herr Sixta of the precise manner in which the female Duckbill supplies her newly-hatched young with milk.

A special feature of the last year or two is the application of American modes of collection and investigation to the smaller mammals of Europe and Asia, with the result that a number of more or less well-defined local races have been established in the case of many familiar European species. Admirable examples of this style of work are afforded by Mr. Barrett Hamilton's studies of the Voles, Dormice, Squirrels, Harvest Mice, and Variable Hares of Europe and Asia. Attention may likewise be directed to the same gentleman's investigations with regard to the colour-change which takes place periodically in many northern mammals.

Till recently the Edentates of South America have been regarded as a totally isolated group; but the material obtained in the Tertiaries of North America has enabled Dr. Wortman to state confidently that they

FIG. 1.—A flightless representative of the Scale-tailed Squirrels (*Zenkerella insignis*). (From Mr. De Winton's figure in the *Proceedings* of the Zoological Society for 1898.)

trace their origin from the Eocene group Ganodontia, as represented by Calamodon and Psittacotherium. The Rodents, too, have been brought into closer touch with more typical mammals by the discovery of their near relationship to the Eocene Tillodontia.

As regards systematic work, the discovery of a new Snub-nosed Monkey (*Rhinopithecus bieti*) in the upper valley of the Mekong is as interesting as it is unexpected; while of far more morphological importance is the description of a flightless representative of the African Scale-tailed Squirrels (Anomaluridæ), for which the name Zenkerella must be adopted. Of even greater interest is Prof. Ray Lankester's discovery (not yet published in detail) that the Bear-like Æluropus of Tibet has no close affinity with the Ursidæ, but is a near relative of the Raccoon-like Panda (Ælurus). Neither have the relationships of extinct forms been neglected, Dr. Major's discovery that the European Lemuroid Adapis agrees in the structure of the tympanic with the Malagasy Lemurs (and with them alone) being of great significance. The same writer's description of additional remains of the extinct Malagasy genera Megaladapis and Nesopithecus throws further light on the specialisation of the Lemuroids, and the apparent parallelism of the latter to Anthropoids. Here brief reference must also be made, even if all his conclusions be not accepted, to Prof. Hubrecht's investigations on the placentation of the Lemuroid genus Tarsius and its relationship to the higher Primates.

Reverting to extinct forms, it has to be mentioned that, apart from its other points of interest, the discovery of a portion of the skin of a Ground Sloth (Glossotherium) in Patagonia has revealed the unexpected fact that the ossicles with which the hide of these animals has long been known to be furnished are situated on its inner instead of its outer surface; the latter carrying a thick coat of long coarse hair.

The discovery some years ago that Wapiti occurred in Central Asia served to call attention to the similarity between the faunas of that region and North America, and the links between the two have now been drawn closer by the description of a species of the American Jumping Mice (Zapus) in Siberia. Another fact of importance from a distributional point of view is the discovery of representatives of the African Hyraces (Pliohyrax) in the Pliocene deposits of Samos and Greece, and apparently also in the Tertiaries of South America. And these discoveries promise to give rise to much discussion as to whether Africa or North America has been the main feeder of South America in the introduction of its fauna. With this is closely connected Prof. Osborn's suggestion that Africa has formed a great creative and dispersive centre of its own.

Mammals cannot be dismissed without a brief reference to the American "Report on the Fur-Seals of the Pribiloffs," which has added very largely to our knowledge of those animals and the diseases to which they are subject; while, it may be hoped, it will serve eventually to suppress altogether pelagic sealing.

Turning to Birds, perhaps the most important work (apart from the description of species and races, to which it is impossible to allude in detail) that has been done in England is by Mr. W. P. Pycraft, who has contributed a number of valuable papers on avian osteology to the *Proceedings* of the Zoological Society, as well as communications to other serials dealing with the general morphology of various groups of the class. Of the former papers, the most important is the one on the skeleton of the Penguins, in which it is shown that these birds are less aberrant than has been often supposed, and that their nearest relatives are the Petrels on the one hand, and the Grebes and Divers on the other. But of even greater value are the same author's observations on the morphology of the Owls (*Trans.* Linn. Soc., 1898), since they serve to indicate how many alterations will be necessary, even in avian genera, when pterylosis and internal characters are allowed their full weight in classification. The remarkable feature of "aquintocubitalism" in the bird's wing has likewise been elucidated by Mr. Pycraft in a paper published in the *Journal* of the Linnean Society for 1899; Mr. P. C. Mitchell having also written upon the same subject. The recent discovery of a new genus of Eagle (*Pithecophaga jefferyi*) by the late Mr. J. Whitehead in the Philippines is also decidedly worthy of mention. Of wider interest is the description by C. W. Andrews, in the *Transactions* of the Zoological Society, of the skeleton of the remarkable giant extinct bird from the Tertiaries of Patagonia, known as *Phororhachus*. This extraordinary bird is noticeable on account of the disproportionately large size of its skull, more especially the beak; and

when the peculiarities due to this specialisation are discounted, its affinities appear to be with the Seriema and Trumpeter of Brazil. It is, in fact, a gigantic representative of that group, occupying the same position in regard to its living allies as is held by the extinct Glyptodons and Ground-Sloths of the same continent to the modern Armadillos, Sloths, and Anteaters.

Among works dealing with avian faunas which have appeared recently, two have a special claim for mention on this occasion; the one being Dr. A. B. Meyer's "Birds of Celebes," and the other the late Mr. A. C. Stark's "Birds of South Africa." Both of these important works have received detailed notice in these columns.

From a distributional point of view, undoubtedly the most important discovery that has been made of late years among Reptiles is the determination of remains of the Australian Tertiary Chelonian genus Miolania in the Patagonian deposits, which was announced last year in this journal by Dr. H. P. Moreno. It serves not only to emphasise the evidence which has been adduced from other sources as to a former land connection between Australasia and South America, but also indicates that the strata in which its remains occur must be comparatively modern. Of very high morphological value are Mr. A. Dendy's observations (*Q.J. Micr. Soc.*, 1899) on the parietal eye of the New Zealand Tuatera (Sphenodon), in which evidence is brought forward to show that this organ was originally double, and that the single eye that now persists in a rudimentary condition is the left one of the primitive pair. In connection with this subject attention may be here directed to the remarkable discovery, made by Mr. H. M. Bernand, that in the Amphibia the cones of the retina of the eye, instead of being separate sensor organs, are merely stages in the development of the structures known as rods. But we have still another word to say with regard to the Tuatera, Prof. G. B. Howes having been recently engaged in working out the development of the skeleton in the embryo, and having had the good fortune to hatch specimens in this country. From his own researches, and those of Mr. Dendy, it is now known that there were three pairs of incisor teeth in the young state, and also that an amniotic tube was present, and that the olfactory passages became occluded during development.

Among Fishes several discoveries and observations of first-class importance have been made during the last few years, in addition to much systematic work. The discovery of a new species of freshwater fish belonging to the genus Galaxias at the Cape may not appear a circumstance of much importance, but it really forms one more link between the faunas of South Africa, Australasia and South America; the genus having previously been known only from the two regions last named. Allied to this genus is the family of African Beaked Fishes (Mormyridæ), hitherto known only by numerous species of the typical genus Mormyrus, and one of the very distinct Gymnarchus. The careful exploration of the fauna of the Congo by the officials of the Free State has, however, led to the discovery of the existence of a very large number of distinct generic types of this very curious family, all of which have been examined and described by Mr. G. A. Boulenger. The first living examples of the Bichir (Polypterus) have also been recently brought to this country, and much information has been at the same time acquired with regard to its mode of life and development. Of still more importance are Mr. J. G. Kerr's observations on the external features in the development of the South American Mud-fish (*Lepidosiren paradoxa*), which were communicated to the Royal Society in the spring of 1899. The young larvæ of this fish, which are tadpole-shaped, have very large external gills, and also a cement-organ very similar to that of embryo frogs, and Mr. Kerr was much struck with the extremely amphibian characters of the larvæ at an early stage of their existence. Among new forms special interest attaches to the discovery of a Shark (*Mitsurikina owstoni*) in Japanese waters, which indicates not only an entirely new generic type, but also, according to its describer, Dr. Jordan (*Proc.* Californian Academy, 1898), likewise a distinct family, whose nearest relationships are with the Carchariidæ. Equally interesting is the discovery in Chili of a new generic type of Lamprey (*Macropthalmia chilensis*), which was announced in 1897. The importance which Dr. Gaskell, in his papers on the origin of Vertebrates, attaches to larval lampreys from a phylogenetic point of view renders the discovery of a new member of this group full of possibilities.

It is too early at present to speak of the discoveries which are likely to occur from the detailed examination of the fishes of the Nile which is now in progress, but reference must be made to those from Lake Tanganyika, described by Mr. Boulenger (*Trans.* Zool. Soc.) in 1898. Although these yielded several new generic and specific types, they were in no wise comparable to the molluscs in general interest.

These latter, as is now well known, exhibit a remarkable resemblance in the form of their shells to certain Jurassic Gastropods; a resemblance which has led Mr. J. E. S. Moore, the energetic explorer of its waters, to suggest that the lake was formerly in direct communication with the sea, and that its so-called "halolymnic" fauna is of marine origin. Some support to this theory may possibly be found in the recent discovery that a peculiar type of Jelly-fish is one of the inhabitants of the lake.

Three other discoveries among Invertebrates call for special mention; one of these being the demonstration by Dr. Pelseener that adult bi-valve molluscs may possess true cephalic eyes, and the second the dredging in Indian waters of a hermit-crab (*Chlaenopagurus andersoni*), whose caudal extremity is protected by a bag formed out of a compact colony of small sea-anemones—truly a most extraordinary example of commensalism. The third discovery is that of a new member (*Harrimania*) of the group of Chordate Worms, or *Enteropneusta*, on the Alaskan coast, to which reference has been recently made in these columns.

So far as the interests of the human race are concerned, all other recent zoological discoveries are eclipsed by the investigations which have led to the demonstration of the relations existing between mosquitoes of the genus Anopheles and malaria. A definite statement that malaria is propagated by these annoying insects was made by Dr. B. Grassi (*Rend. Ac. Lincei*, vii. p. 234) in 1898, with due acknowledgment of previous suggestions on the subject; and since that date the columns of this journal have borne testimony to the zeal and care with which the work has been carried on, and the decisive results which have been obtained. In connection with this subject, brief mention must be made of the discovery of the generative elements in the intracorpuscular amœba-like bodies known as Hæmamœbidæ, which occur in the blood of certain animals and give rise to malarial fever, as well as in the allied Coccidiidæ, which are parasitic in Cuttle-fish. As is shown in two papers published in the July number of the *Quart. Journ. Microscopical Science*, sexual conjunction, or "zygosis," occurs among these lowly organisms; spermatozoa being represented by "microgametes," and ova by "macrogametes."

Finally, some reference must be made to the important work on distribution which has been accomplished during the last few years. In this connection it will suffice to refer to Mr. R. F. Scharff's "History of the European Fauna"; to Mr. W. L. Sclater's papers on the "Geography of Mammals," first published in the *Geographical Journal*, and reproduced in volume form with much

additional matter; to Dr. P. Matschie's "Geographische Fragen aus der Saugethierkunde," published in 1896; to Mr. R. I. Pocock's "Geographical Distribution of the Arachnida," which appeared in *Natural Science* for 1899; to Dr. Max Weber's paper on the "Origin of the Fauna of Celebes" (*Ann. Nat. Hist.*, 1899); and, lastly, to Prof. H. F. Osborn's "Correlation between Tertiary Mammal Horizons of Europe and America" (*Ann.* N. York Acad., 1900). In several of these papers special stress is laid on the evidences of connection between the faunas of the southern continents which have been steadily accumulating during the last few years; while, as already mentioned, Prof. Osborn's communication is notable on account of his theory as to the indigenous origin of the African fauna. In another part of the world a most important change in the limits of two geographical regions has been suggested (first by Mr. Sclater and then by Dr. Weber), by the transference of Celebes from the Australian to the Oriental region. If this change, together with a similar transference in the case of Bali and Lombok, which has been advocated (partly on the suggestion of Dr. Blanford) by the present writer, be generally adopted (and it seems inevitable), we have to bid farewell for ever to the almost classic "Wallace's Line," as being one of those hypotheses which, although useful in their day, were not destined to immortality. R. L.

INSTRUMENTS OF PRECISION AT THE PARIS EXHIBITION.

"AT the commencement of the nineteenth century, the French and English makers of scientific instruments were far in advance of the Germans. True, the eighteenth century knew of prominent mechanicians . . . yet the French and English makers took the lead so as almost to supply the world's entire demand in scientific instruments. This predominance had the further consequence of causing young Germans to emigrate to France or England in order to thoroughly master their subject. Many a German mechanic of to-day owes to French or English masters a substantial portion of his knowledge. The prominence of the French and English instrument makers was mainly due to the support which, in both countries, the State bestowed upon technical art." . . . "In Germany it is only within the last twenty or twenty-five years that the State has espoused the interests of the home industry in scientific instruments; but such have been the efforts and the results, that her position has, at a blow as it were, changed in favour of Germany."

These words are taken from the special catalogue of the joint exhibition of German mechanicians and opticians at the Paris Exhibition, which claims, and claims with truth, "that in this department Germany occupies now a foremost position." As to the excellence of this joint exhibition, it is difficult to speak too strongly; rumour says that some, at least, of the judges wished to award it a Grand Prix among the nations. Had the rules of the Exhibition allowed it, such an award would have met with the universal approval of all physicists who have visited Paris.

Another brief quotation from the preface will explain the position more clearly. "After witnessing," the writers say, "the steady development of our mechanical and optical trade, we cannot but look with gratification upon the practical demonstration, at the Paris Centenary Exhibition, of the flourishing state of the scientific instrument trade in Germany; and a characteristic feature of the latter is the unity of its aims, which is traceable to the history of its development and to its ultimate connection with pure science. It appeared, therefore, desirable to depart from the usual custom of grouping the exhibits under various firms, and to place them in sections embracing certain classes of instruments, so as to demonstrate on broad lines and, as a whole, within a well-arranged though condensed area, the present position of German mechanical and optical art."

Accordingly this was done under the auspices of the German Association of Mechanicians and Opticians, and, with the help of the authorities of the Reichsanstalt and of the Standardising Commission, a most remarkable exhibit has been arranged; a catalogue has been prepared, covering some 250 small quarto pages, well illustrated, with a full account of the various instruments and references to sources of further information. This is published in German, French and English—why the English edition is printed in German type is perhaps somewhat of a mystery—and issued freely to visitors who wish to use it.

The preface to this catalogue, from which the above extracts are taken, gives an interesting account of the growth of this industry, from which it appears that in the last ten years the annual value of the instruments exported, including the optical glass used for lenses, has risen from something over 200,000*l.* to over 700,000*l.*

The general exhibition is arranged in ten sections, with various subsections; the special exhibit of the Reichsanstalt forms an eleventh section to itself. In each of these sections or subsections the exhibits of each maker form a class to themselves.

Thus Section V., optical instruments, has seven subdivisions. The exhibit of Carl Zeiss, for example, appears in five of these, as well as in Section II., astronomical instruments. By means of the table of contents and list of exhibitors, it is easy for a visitor to find either the apparatus of a special class or the exhibit of a particular firm as he will.

Section I. contains metrological and standardising apparatus, and here the exhibit of the Normal Aichungs Commission is most striking. The Commission is presided over by a director, and includes, we are told, three Government councillors, twenty-four technical officials, and ten clerks; the annual expenditure is 8500*l.* Contrast this with the staff of our Standards Department, and its expenditure, according to Whitaker, of 2877*l.* Specially noteworthy, perhaps, among the exhibits of the Aichungs Commission are the model of their great comparator, and the vacuum balance made by Stückrath for comparing masses from 200 grammes to one kilogramme. But a detailed description of the catalogue would take too much space, and would indeed be of no great value to a reader; the book itself will prove to a physicist a well of useful information; the exhibit, however, must be seen in its entirety if we wish to realise what our German cousins have done.

Not that the sight is one which brings great pleasure to an Englishman, and if he moves on to examine the English exhibit his thoughts cannot fail to be very grave. There is nothing which can be compared with the German show; some well-known firms have won well-deserved prizes; there are some few interesting pieces of apparatus from South Kensington, and here and there in the electrical department one comes across a case of instruments. For the rest, the visitor will find, not collections of scientific apparatus, but small portions—attractive portions, it is true, in many cases—of the windows of well-known opticians' shops. As much apparatus as is possible is packed together in a small space, there is much repetition, there is no organisation, there is no attempt to instruct the learner or to attract the man who comes with inquiries with a view to purchase; English mechanics and opticians have no unity of aim, and their art, with some few exceptions, is but loosely linked to pure science.

A visitor who visits Paris to look for the most recent forms of scientific apparatus must have the conviction

forced on him that it is to Germany he must go for his goods.

And the conviction is strengthened by the organisation provided for giving information as to the goods exhibited. The German exhibit is under the skilled care of Dr. Robert Drosten, with some three or four scientific assistants. One or more of these gentlemen is always ready to give information about special instruments. When I visited the exhibition I asked for a catalogue, and inquired if I could examine more closely certain special instruments. By all means, was the reply, and Herr Drosten gave me several hours of his time opening cases, taking apparatus out, looking up special catalogues, and loading me with information. At the end of this time we were both tired, and he suggested that if I found, on looking over the catalogue and my notes, that I had omitted anything, I should come again. I returned next morning, and spent nearly as long a second time.

Or take, again, my own experience with the splendid exhibit of comparators and dividing engines of the Société Genevoise des Instruments de Précision.

There was a notice in the case that M. Schwartz, at the Bureau, would give information. On asking for M. Schwartz, and explaining that I wished to examine certain things with care, he came at once, opened the cases, and answered my many questions in the most courteous manner; some information which I wanted as to certain instruments not made by the Society he could not give me. It has since been sent me, at his request, from Switzerland.

So also with some American measuring and testing apparatus; the cases were opened, and I was allowed to handle the apparatus; one gentleman gave me a very full demonstration of the use of a new testing machine, which combines a multitude of ingenious devices.

Contrast this with the English exhibit; a courteous commissionaire was, when I saw it, in charge of the whole; there were some notices as to where to apply for price lists of some of the firms exhibiting; the nearest approach to a catalogue was a set of cards hung on the wall relating to the excellent exhibit of the Scientific Instrument Company. These I found of real value, but they could not be carried away for reference.

Again the same conclusion is forced home; the Germans have organised their exhibit and are far ahead; few, if any, of the English firms will profit through the exhibition by an increase in their trade; German trade must grow as a result of a show which has been visited by thousands of men of science. The 700,000*l.* of 1898 will rapidly increase.

And why should this be so? Is it our insular ignorance and our unreadiness? In everything, this great exhibition shows the advance of our continental rivals. It is probably true that, in the special circumstances of the exhibition, many prominent firms declined to exhibit. The results will prove conclusively that they made a mistake. Why should I exhibit? said one manufacturer; last time I sent the best of my goods and won a prize, and the French immediately put on heavy duties against them. It is an argument that may have some weight, but does not apply forcibly to scientific apparatus; besides, the French are not the only customers. No; the reason lies deeper. British pluck and doggedness, the individual skill of the British workman, which, on the average, is far above that of his foreign *confrère*, the traditions of British ascendancy in the past, can all do much, but we have not realised—shall we realise them in time?—the efforts our continental rivals are making to rob us of that ascendancy. It is true, as a recent writer in the *Westminster Gazette* puts it, speaking of trade with South Africa, that

"We must be prepared to face the truth that, unless the British manufacturer bestir himself for the supply of this great African community, a great deal of business which, in the natural course of events, should go to him will certainly have to be diverted to Germany and America."

The first step towards curing the disease is to recognise its presence; and how slow we are to do that.

The German catalogue and the exhibit are striking evidences of the services rendered to German trade by the Reichsanstalt.

"The greatest share of the impetus given to the manufacture of scientific instruments," says the catalogue, "is due to the Imperial Physical and Technical Institute. . . . This institution has already done great service, and a large proportion of recent progress is due to its stimulating and helpful influence."

An inspection of the exhibit fully bears this out. We in England have for some time past hoped that the National Physical Laboratory would do for English science all the Reichsanstalt has done for Germany.

It is now two years since the Treasury accepted generally the conclusions of the report of Lord Rayleigh's Committee on the establishment of such a laboratory, and one year since the first meeting of the General Board, and for months the whole scheme has been at a standstill because certain of our rulers attach more weight to the protests of some who object to the selected site than to the deliberate opinion of those whom they have invited to organise and control the laboratory.

It is admitted that the establishment of the laboratory is of national importance. Various difficulties are allowed to delay its erection; meanwhile the Germans go ahead.

Up to the middle of the century our methods were sufficient; that condition of things has ceased. The organised application of science and scientific methods to trade and commerce, indeed to all the affairs of life, is absolutely essential if we are to continue to prosper. Will England realise this truth before it is too late?

NOTES.

THE evening discourses at the meeting of the British Association at Glasgow next year will be given by Mr. Francis Darwin, F.R.S., and Prof. W. Ramsay, F.R.S. The lecture to working men will be delivered by Mr. H. J. Mackinder.

HUXLEY'S life and work is an inspiring subject for a lecturer, and Lord Avebury had no difficulty in interesting the audience which assembled at the Museum of Practical Geology on Tuesday to hear him discourse upon it. The address was the first of the annual lectures established by the Anthropological Institute in memory of Huxley; and as Lord Avebury was a close and intimate friend of the master, he very appropriately inaugurated the series. Readers of NATURE are familiar with a large part of Huxley's work, but a few points mentioned by Lord Avebury will bear repetition. Huxley's Friday evening lectures at the Royal Institution rivalled those of Tyndall in interest and brilliancy; yet he said himself that at first he had almost every fault a speaker could have. He was one of the foremost of those who brought people to realise that science is of vital importance in their lives, that it is more fascinating than a fairy tale and more thrilling than a novel, and that any one who neglects to follow the triumphant march of discovery, so inspiring in its moral influence and its revelations of the beauties and wonders of the world, is deliberately rejecting one of the greatest interests and comforts of life. Apart from his professional and administrative duties, Huxley's works fall into three principal divisions—science, education and metaphysics. Of his contributions to science the Royal Society's catalogue enumerates more than one hundred, and every one of them, in the words of Prof. Parker, "contained some brilliant generalisation, some new and fruitful way of looking at the facts." The value of his

services to education cannot be over-estimated. He maintained that no boy or girl should leave school without possessing a grasp of the general character of science, and without having been disciplined more or less in the methods of all sciences. As regards higher education, he was a strong advocate for science and modern languages, though without wishing to drop classics. There were two things which he said he really cared about—one was the advance of natural knowledge, and the other the bettering of the condition of the masses of the people. How well he furthered both scientific and national progress is known to all of us.

PROF. A. CALMETTE, director of the Pasteur Institute at Lille, who is giving the Harben lectures this year, at the Examination Hall of the Royal College of Physicians and Surgeons, has taken the plague as his subject. In his first lecture, delivered on November 7, he pointed out that plague now menaces all the maritime nations of the globe, and it has become necessary to take rigorous measures to stop its extension. The progress of hygiene and the knowledge acquired during the last five years on the etiology, treatment and prophylaxis of the affection enables it to be combated very efficaciously and its centres to be rapidly circumscribed. It is known that the plague bacillus is found in the buboes and sputa of the patient, that it is also frequently found in the blood, that it has the form of a short bacterium, slightly ovoid, that it is easy to stain by the ordinary laboratory methods, and that it can be cultivated on the usual media. Mice, rats and guinea-pigs show the greatest susceptibility to plague. It has long been remarked that in localities where the plague appears mice and rats die in great numbers, and from the most ancient times, and even to-day, the Chinese and nomadic peoples inhabiting the northern slopes of the Himalayas, so soon as they notice an abundance of dead rats, remove elsewhere to avoid the epidemic they know must be at hand. Of other animals the pig and ox are said to be subject to the plague, but observations show that they cannot take the disease, at least spontaneously. Nor can birds easily contract it; the vultures that devour the corpses of the plague-stricken in the Towers of Silence in the suburbs of Bombay suffer no ill after their funereal repast, though they may distribute plague microbes through their excreta. A monkey was found to contract the plague spontaneously when placed in a cage side by side with another monkey; in this and similar cases the infection was apparently carried by flies or by fleas and other parasites of the skin.

IN connection with the International Exposition at Paris, a number of balloons recently ascended from Vincennes with the object of testing which could remain in the air for the longest period. *La Nature* gives the following results:—Count Henri de la Vaulx descended, after a journey lasting 35h. 45m., at Korostichew, in Russia, the distance from the starting-point being 1925 kilometres, and the greatest altitude 5700 metres. M. Jacques Balsan descended after a voyage of 27h. 5m., having attained a maximum altitude of 6540 metres, and reached a distance of 1345 kilometres from the starting-point. M. Jacques Faure descended in Germany, 950 kilometres from the starting-point, after a journey of 19h. 24m. Upon these results, and those of previous contests, the grand prize in aeronautics has been awarded to Count Henri de la Vaulx.

M. DE FONVIELLE informs us that Dr. Janssen has asked the Aero-Club at Paris to organise a series of three balloon ascents on the nights of Tuesday, Wednesday and Thursday of this week, in order to see whether the Leonids make an appearance or not.

A PAN-AMERICAN EXPOSITION will be held at Buffalo, New York, from the beginning of May to the end of October next year. There will be a large building for electrical exhibits, and in it will be the service plant, for the transformation and distribution of the 5000 horse-power transmitted from Niagara Falls, for lighting and power purposes; a collective exhibit of historical interest, containing illustrative models and apparatus showing important advances in the art; and the commercial exhibit, showing articles possessing distinctive merit, whether consisting of workmanship, novelty or usefulness.

THE opening meeting of the new session of the Society of Arts, the 147th since the foundation of the society in 1754, will be held on Wednesday evening, November 21, when an address will be delivered by Sir John Evans, K.C.B., F.R.S., vice-president and chairman of the Council. For the meetings previous to Christmas the following arrangements have been made:—November 28, Major Ronald Ross, "Malaria and Mosquitoes;" December 5, Prof. H. S. Hele-Shaw, F.R.S., "Road Traction;" December 12, Prof. Frank Clowes, "The Treatment of London Sewage."

AT a recent meeting of the committee of the Liverpool School of Tropical Medicine it was unanimously resolved to invite Dr. R. Fielding Ould, Dr. Balfour Stewart and Dr. A. S. Grünbaum to become assistant lecturers. These gentlemen have already assisted the work of the school in many different ways. On the motion of Mr. Alfred L. Jones it was resolved that the best thanks of the school are due to Drs. Annett, Dutton, and Elliot for their very valuable services in West Africa whilst members of the second malarial expedition of the school. These gentlemen have just returned, bringing with them a quantity of valuable material for future work.

RENEWED interest in the mosquito theory of the propagation of yellow fever, propounded by Dr. C. I. Finlay, of Havana, is aroused by a paper read at the recent meeting of the American Public Health Association at Indianapolis, by Surgeon Walter Reed and Assistant-Surgeons J. Carroll, A. Agramonte and J. W. Lazear. From experiments and observations made in Cuba, in the course of which Dr. Lazear died from yellow fever apparently conveyed to him by an infected mosquito, the following conclusion is arrived at:—"The mosquito serves as the intermediate host for the parasite of yellow fever, and it is highly probable that the disease is only propagated through the bite of this insect."

THE *Times* states that the whaler *Eclipse*, which arrived at Dundee on November 7 from Davis Strait, landed Dr. Leopold Kann, who has for eighteen months been connected with a scientific expedition to the Arctic regions. The expedition, which consisted of Dr. Kann, Mr. Robert Stein, of Washington, U.S.A., and a Boston taxidermist named Mr. S. Warmbath, left Sydney, Nova Scotia, in July 1899, on board the Peary relief ship *Diana*. The Peary expedition was seen in the beginning of August 1899, in three divisions. At that time Lieutenant Peary had been badly frostbitten, having lost several toes, and being only ably to walk with difficulty. The party, which had a large number of sledges and Eskimo dogs, was determined to make a dash for the North Pole.

ARRANGEMENTS have been made for the issue, by the Cambridge University Press, of a journal devoted to the publication of the best original work on hygiene. The periodical will be entitled *The Journal of Hygiene*, and will be issued quarterly. It will be edited by Dr. G. H. F. Nuttall, in conjunction with Dr. John Haldane, F.R.S., and Dr. Arthur Newsholme. The scope of the new journal will be similar to that of the *Archiv für Hygiene* and *Zeitschrift für Hygiene*, and the aim will be to become the chief medium for original workers in hygiene among English-speaking people. The first number of the journal will appear on January 1, 1901.

IN several parts of Germany considerable attention is being paid to electrical appliances that can be used on the farm. Mr. Hughes, U.S. Consul at Coburg, reports that near Ochsenfurt, in Bavaria, a company, composed of land-owners and small farmers, has been organised for the establishment of an electrical system for use on their farms and in villages. The power is to be generated by steam and water, and the current to be distributed from a central station to the places at which it is wanted. Sub-stations are to be established at given points, with the necessary apparatus for connecting with the farm or other machinery, and also for lighting purposes in the houses, offices, roads, and village streets.

FROM the U.S. *Experiment Station Record* (vol. xii., No. 1), we learn that an interesting step, looking to the advancement of agriculture in the Russian Empire, has recently been taken, on the recommendation of the Ministry of Agriculture and Imperial Estates, in the inauguration of a system of commissioners of agriculture to preside over the agricultural affairs in their respective provinces or governments, and to seek to prom ote and improve the agricultural conditions in general. Provision has been made for such commissioners in twenty differe nt governments of the Empire, and the funds for their maintenance became available with the beginning of the present year. These commissioners will have charge of all public measures relating to agriculture and rural affairs, and will exercise supervision over all local agricultural institutions maintained by the government. They will inquire into the agricultural needs of their respective governments, and will r ecommend government aid for such local or private enterprises as merit special encouragement. Connected with the commissioners' offices will be corps of agricultural specialists and instructors, who will be assigned to the work by the Ministry of Agriculture and Imperial Estates. They will go out among the landowners and peasants for the purpose of collecting data regarding the actual conditions of various branches of agriculture, to diffuse general information on agricultural topics, and endeavour to improve the methods and practices in vogue. The inauguration of this system would seem to be a distinct mark of progress. Taken in connection with the recent decrees regarding the establishment of addition al agricultural experiment stations and systems of agricultural education, already referred to, it should materially improve and modernise the practice of agriculture in Russia.

A SIMPLE method of recording the speed of motor cars and other vehicles has been devised by M. L. Gaumont, and accounts of the device appear in *Cosmos* and *La Nature* of November 3. The instrument consists simply of a camera with a double shutter, by which two exposures are made of the same plate, separated by a known interval of time. On developing the photograph two images are obtained of the moving object, and, by measuring the distance between them, the dimensions of the car being supposed known and also measured on the plate, it is easy to calculate the speed of the car at the instant when the photograph was taken. The object is to assist the authorities in regulating the speed of these vehicles and checking furious driving.

THE Cancer Society has just issued its annnal report, from which we learn that one of the great aims of the Society has been to direct public attention to the insidious danger threatening in the increase of cancer. During the past year the Committee have sent out Dr. Arthur C. Duffey to the United States to report on the equipment of the newly-erected Cancer Laboratory at Buffalo, and on his return a detailed report was issued to all the medical schools and to the Press. A prize of fifteen guineas, offered by Miss Scott for the best original essay on the present state of cancer science, has been awarded to Dr. Alexander Fraser, of Manchester. An elementary pamphlet by Dr. Herbert Snow, laying down maxims for the avoidance and early recognition of cancer, has been issued, together with numerous other publications bearing on the subject.

DR. QUIRINO MAJORANA contributes to the *Atti dei Lincei* an account of experiments dealing with the behaviour of carbon at high temperatures and pressures. In M. Moissan's experiments on the transformation of diamonds, the partial crystallisation of the carbon was attributed to (1) the high temperature of the central mass, (2) the solubility of the carbon in the metallic mass, and (3) the pressure. Dr. Majorana, finding that in his previous experiments the crystals obtained were much smaller than those produced by Moissan, has conducted a fresh series of experiments in which he has maintained the carbon at a pressure exceeding, and a temperature equalling, that employed by Moissan, for a considerably longer period of time, without producing so marked an increase of density. From this he considers it probable that the solubility of the carbon in the surrounding medium is one of the principal factors in the crystallisation.

A SERIES of papers dealing with the properties of pozzolana, and its use in mortars and cements exposed to the action of sea-water, is contributed to the *Gazzetta chimica italiana* by M. O. Rebuffat. In one of these papers the author discusses the reactions of the several silicates of alumina entering into the composition of pozzolana, with especial reference to the production of artificial cements of this character. In con nection with the action of sea-water, the principal results are that sea-water transforms the cement of mortars containing pozzolana into a hydrated silicate of alumina containing small quantities of lime and magnesia and quantities not negligible of alkalis. The silicate, by its composition, is altogether unaffected by the salts of sea-water. Seeing that in mortars immersed in sea-water the lime, after binding the mortar together, ultimately disappears completely, the use of mixtures of cement and pozzolana is not recommended. The author advocates the old plan of screening the pozzolana, and deprecates the use of finely ground pozzolana mixed with sand.

PROF. R. SISSINGH, of Amsterdam, has published a short treatise on the general properties of images formed by direct pencils traversing a system of spherical surfaces. This treatise contains a simplification of the proofs applicable to an optic system formed of lenses centred on the same axis. The theory now offered is essentially physical in character; at the same time, the ordinary geometrical properties of images are also established, and the optical properties of the eye are considered. Prof. Sissingh takes no account of aberration other than chromatic aberration. The monograph is reprinted from the *Verhandelingen* of the Royal Academy of Amsterdam, and published by Johannes Müller, of Amsterdam.

WE have received from Sir Charles Todd, Government Astronomer of South Australia, a report upon the Rainfall of the Colony during 1897, showing the monthly and yearly values at 415 stations, together with the number of days on which rain fell, the greatest fall in one day, and the mean of the rainfall for a number of previous years. The rains during the year were irregular and, on the whole, below the average over the whole colony; in October a dry spell set in, which lasted during the rest of the year, and practically ruined the agricultural prospects. As an instance of the lengthy drought to which places in the interior are subject, Charlotte Waters in 1896 had 2·84 inches only, and 1·16 inches in 1897. A valuable table is given, showing the yearly rainfall at Adelaide for 59 years from 1839 to 1897, and the years when the amount was above or below the general average (20·886 inches) for the whole period.

WE learn from the U.S. *Monthly Weather Review* that the Russian Meteorological Office has published a comprehensive meteorological atlas, to commemorate the fiftieth anniversary of the foundation of the Central Physical Observatory by the Emperor Nicholas I. on April 1, 1849. It contains eighty-nine charts and fifteen graphical tables, and exhibits the prominent features of the climate of the Russian Empire from Warsaw on the extreme west, to Bering Strait on the east, and from Teheran on the south, to the Arctic Ocean. This range of 40° of latitude and 160° of longitude represents one of the most extensive meteorological systems in the world. The mean values of all the principal elements are exhibited in monthly and annual charts, the rainfall being shown for seasons. One of the charts shows the number of days during which snow lies on the ground; the region of the maximum number of days (190) extends from Archangel east-south-eastward beyond the Ural. From this region the number of days diminishes until we reach sixty days on the northern shores of the Caspian Sea, and twenty days on the north-western shores of the Black Sea. The paths of cyclones and types of weather in Russia, in so far as the latter depend on barometric conditions, are shown by five charts. The whole work is pronounced by the U.S. Weather Bureau to be a magnificent production, and illustrative of the activity of this vast meteorological service.

THE *American Museum Journal*, of which we have received the third part, appears to be a publication well worth the attention of museum authorities in other countries. It is issued monthly, and is stated to be a popular record of the progress of the American Museum of Natural History; the present part, which is well illustrated, containing fifteen pages of text. The first article is an obituary notice of the late Mr. J. M. Constable, the Vice-President of the museum. This is followed by a record of recent donations to the library, and this again by a reference to an exhibit displaying the fauna of New York, which has been recently added to the museum and appears to have attracted much attention from the public. Other articles describe the development of the museum, the work and progress of the Department of Public Instruction, and the work which has been recently accomplished in the anthropology of the Pueblo and Cave-dwelling Indians of New Mexico and the adjacent territories.

THE feature of the *Entomologist* for November is the continuation by Dr. Max Standfuss of the account of his experiments in hybridisation among the Lepidoptera, and the effects of temperature on those insects; the paper being illustrated by a plate of abnormally coloured butterflies. As regards these abnormalities (several of which occur occasionally in nature) produced by temperature variation, the author considers that they are not atavistic. A large proportion of them are infertile, and the majority of those which bred produced normal offspring, only the most abnormal female transmitting more or less of its newly acquired characters to its progeny. Although the experiments, on account of disease, were incomplete, their result, so far, seems to demonstrate that the possibility of perpetuating the abnormalities depends on the degree to which these depart from the ordinary form.

THE *Transactions* of the New Zealand Institute for 1899 contains thirteen papers on zoology, seven on botany, and five on geology, the great majority relating to the colony itself. Of especial interest is the record, by Prof. Benham, of the occurrence of a species of Balanoglossus in New Zealand waters, while a note on the freshwater crayfishes of the colony, by Dr. C. Chilton, will attract the attention of students of the crustacea. The practical extermination of the great purple coot (*Notornis mantelli*) is attributed by Mr. R. Henry very largely to rats, which, by eating the wild grain and seeds, prevent the bird from obtaining its proper nutriment. It will be news to many ornithologists that, about twenty years ago, the ship *Gleaner* came into Greymouth with a strange bird on board which turned out to be either the New Zealand or the Australian giant coot, and had reached the vessel at a distance of 400 miles from the shore. These birds were supposed to be practically incapable of flight.

WE have received from the U. S. Department of Agriculture, No. 19 of the "North American Fauna," which describes the results of a biological reconnaissance of the Yukon river region. The memoir is divided into three sections, of which the first is devoted to a general account of the region, while the second and third respectively treat of the mammals and the birds. For the latter Dr. L. B. Bishop is responsible, the two former sections being the work of Mr. W. H. Osgood. Although the whole area belongs to what American writers term the boreal zone, it has been found possible to divide it into several formal districts, the *tundra* being assigned to the Arctic province, while the Yukon Valley itself comes mainly within the Hudsonian division, but also contains a distinct Canadian element. In addition to several which have been described a short time previously, the memoir notices three birds and nine mammals which are regarded as new. It seems, however, pushing refinements of distinction a little too far to regard the two forms of reindeer met with in Alaska, as well as the elk, as distinct species.

PART ii. of vol. lxviii. of the *Zeitschrift für wissenschaftliche Zoologie*, which has just reached us, contains two papers; one, by Herr Samter, an elaborate dissertation on the development of the crustacean *Leptodora hyalina*, the other, by Herr S. Metalnikoff, an account of the anatomy and histology of the worm *Sipunculus nudus*. Both communications are exquisitely illustrated.

To the August number of the *Journal* of the Bombay Medical and Physical Society, Dr. N. F. Surveyor contributes an illustrated account of the parasitic invasions to which the eggs of the cockroach are subject. These include two Hymenoptera, several kinds of moulds, probably several beetles, possibly another cockroach-like insect, and the parent itself. The importance of the subject will be apparent when it is stated that several of the parasites of the cockroach may pass a portion of their existence within the body of man himself.

IT has been shown by Dr. C. L. Griesbach, the Director of the Geological Survey of India, that the Trias of the Himalaya contains several well-marked horizons of Cephalopods not only in the Muschelkalk, but above and below it. The rich series of specimens collected in recent years has been submitted to Dr. Edmund Mojsisovics of Vienna, and he has written an elaborate memoir on the Upper Triassic species ("Palæontologia Indica," Ser. xv. Himalayan Fossils, vol. iii., part I., 1899). This memoir has been translated into English for the Indian Survey by Dr. and Mrs. A. Foord. The main portion of the work is naturally devoted to a description of the species, which are ranged under genera, whose characteristics can be understood only by those palæontologists who devote particular attention to the subject. Among the genera familiar when General Strachey first discovered Triassic fossils in the Himalaya, *Ceratites*, *Nautilus* and *Orthoceras* alone appear, but a host of others, needful to express the results of modern discrimination, find place in the volume. Of most interest to geologists are the general results arrived at by Dr. Mojsisovics. He refers to the local character of the Indian Upper Triassic fauna, but observes that there can be no doubt of the former existence of an open connection of the sea between the Indian and Mediterranean provinces. The Indian Trias province forms an integral part of

the "Thetys," or great Trias sea, named by Ed. Suess, which extended from the Mediterranean eastwards through Central Asia, and included the Germanic shallow sea. Some remarks are also made on the Arctic-Pacific Trias Province.

THE geology of Bad Nauheim and its thermal salt-springs form the subject of an interesting article by Mr. A. Vaughan Jennings (*Geological Magazine*). He notes the fact that, sixteen centuries ago, Bad Nauheim was a Roman sanatorium, its fame arising from the small natural springs of thermal water. During the present century several borings have been made to largely increase the supply of water; the last one, made in 1855, was carried to a depth of 180 metres. The water appears to be pent up in a basin of Devonian rocks covered by Tertiary strata. The author discusses the source of the water, its temperature and saline ingredients.

THE Essex Field Club has issued, as No. 4 of its museum hand-books (price 2*d.*), a sketch of the crag formation of East Anglia, by Mr. W. H. Dalton.

WE have received Nos. 21 and 22 of *Spelunca*, or *Bulletin de la Société de Spéléologie*, which contains a variety of information about caves and water-channels, with notices of recent publications.

THE growth and retreat of Norwegian glaciers is dealt with by Mr. J. Rekstad (*Norges Geol. Undersogelse*, No. 4). He draws attention to the evidence of great fluctuations in the amount of ice extending over periods of at least two hundred years, and remarks that these periods of general increase or decrease are accompanied by minor oscillations in the glaciers.

MR. R. BULLEN NEWTON has described some marine mollusca from the Upper Trias in the Malay Peninsula. These include the well-known and widely distributed *Chlamys* (*Pecten*) *valoniensis*, as well as species of *Pleurophorus*, *Myophoria*, &c., which indicate the horizon of the Rhætic beds (*Proceedings*, Malacological Soc., Oct. 1900).

THE newly-appointed Government Geologist of Queensland, Mr. W. H. Rands, has forwarded a copy of the annual progress report of the Geological Survey for 1899. He takes occasion to express the general feeling of regret at the resignation of his predecessor, Mr. R. L. Jack. The report, which deals mainly with copper, gold, and coal properties, includes contributions by Mr. B. Dunstan on the occurrence of oriental ruby in northern Queensland, and on fire-clay.

CANON SCOBELL contributes to the *Proceedings* of the Cotteswold Club (vol. xiii. part iii.) some interesting notes on the common fields at Upton St. Leonard's, and these are accompanied by a view of lynches, which indicate the ancient system of ploughing in strips and terraces. In some excursion notes Mr. S. S. Buckman deals with river features in the phraseology used by Prof. W. M. Davis. He refers also to the tunnel near Chipping Sodbury on the South Wales direct railway, to the water therein encountered, and to the probable effects consequent on its diversion by pumping.

To the *Bulletin* of the American Geographical Society, vol. xxxii., 1900, Mr. R. L. Barrett contributes an interesting account of the Sundal drainage system in central Norway. The author explains the curious "reversal of drainage" which has occurred in this region, and deals with the question of the "hanging valleys" and erosion by overflowing glaciers.

IN a paper brought before the Academy of Sciences of Cracow, Mr. L. Marchlewski has described a new derivative of chlorophyll. This substance, which its discoverer has named phyllorubine, differs considerably from the previously known phylloporphyrine, another chlorophyll derivative. While the spectrum of the latter is distinguished from that of other chlorophyll derivatives by having no band in the red region, phyllorubine forms no such exception. The new substance has not yet been obtained in the crystalline state.

THE action of chemical solutions on the lower forms of life is the subject of two papers in German in the *Journal* of the College of Science, Imperial University of Tokio—one, by N. Ōno, dealing with their effect on the growth of algæ and fungi, while the other, by Prof. Atsushi Yasuda, treats of the adaptability of infusoria to concentrated solutions. The former author finds that certain poisons in a highly diluted state favour the growth of the lower algæ, that smaller "doses" are required with algæ than with fungi, that mercury chloride and copper sulphate in certain degrees of dilution favour the growth of fungi (a remarkable result, seeing that corrosive sublimate in stronger concentration is used as a preventive of mildew), and that spore-formation is retarded by certain chemicals. Prof. Yasuda, on the other hand, finds that infusoria are affected by a much lower degree of concentration than algæ and fungi, even the most resistive species, *Euglena viridis*, being unable to exist on any but relatively weak solutions. An account is given of the physiological changes which take place in the organisms as the degree of concentration is varied.

A PRELIMINARY note on the fungi collected in the Belgian Antarctic Expedition is contributed to the *Bulletin de la Classe des Sciences* of the Belgian Academy by Mesdames Bommer and Rousseau. Almost all of these come from Tierra del Fuego. One species alone was found in Dango Land, *i.e.* the Antarctic region proper; but this species has not been classified, as it is represented only by a sclerotium, without carpophore. Among the fungi of Tierra del Fuego, out of fifteen species collected ten were new.

DR. GEORGE NEWMAN'S book on "Bacteria," published a year ago in Mr. John Murray's Progressive Science Series, and reviewed in these columns (vol. lx. p. 434, September 7, 1899), has met with the success which its excellence deserves. A new edition has been issued, with additional matter, including new chapters on tropical diseases and on the bacterial treatment of sewage.

THE second volume of the new edition of the well-known "Gardener's Assistant," which has been revised and entirely remodelled under the direction and general editorship of Mr. William Watson, of the Royal Gardens, Kew, has just been issued by the Gresham Publishing Company. The work, so far as it has gone, is thoroughly in touch with the spirit of modern gardening, and should be in the hands of every practical horticulturist.

MESSRS. WILLIAMS AND NORGATE'S *Book Circular* is known to many men of science as a useful guide to foreign scientific works, containing not only the titles and other publisher's particulars, but also notes describing the scope and character of the contents. Eight of these circulars, referring to works published during last year and this, have now been issued in volume form, and the book thus produced is a handy catalogue of important scientific publications which have lately appeared.

ANOTHER part of Engler's "Monographieen Afrikanischer Pflanzen-familien und-Gattungen" has been received; and in it Dr. K. Schumann deals with the African Sterculiaceæ. The work is being prepared, regardless of expense, under the auspices of the Berlin Academy of Sciences, and is published by W. Englemann, Leipzig. The trustees of the British Museum (Natural History) have just published a new part of the "Catalogue of the African Plants collected by Dr. Friedrich Welwitsch in 1853-61." This is the fourth (and concluding) part of Mr.

W. P. Hiern's description of the dicotyledonous plants collected by Dr. Welwitsch, the first having been published at the end of 1896.

THE *Bibliotheca Geographica*, edited by Dr. Otto Baschin for the Berlin Geographical Society, is known to be a most complete annual and international bibliography of geographical literature. The sixth volume of this catalogue contains the titles of papers published during 1897, classified into the usual groups according to subjects, and with an authors' index. It is thus possible to find, without the slightest difficulty, what papers upon any particular district or branch of geography were published in 1897, or to look up the list of publications of any writer on geographical subjects. The volume contains 444 pages, and it does credit to the editor and the society under whose auspices it has been prepared.

THE additions to the Zoological Society's Gardens during the past week include a Lioness (*Felis leo*) from East Africa, presented by Major T. Soutar, Cameron Highlanders; a Sooty Mangabey (*Cercocebus fuliginosus*, ♂) from West Africa, presented by Major G. McMicking, commanding C.I.V. Field Battery; two Ostriches (*Struthio camelus*), a Nilotic Crocodile (*Crocodilus niloticus*) from East Africa, presented by Mr. G. Marsden; an Egyptian Jerboa (*Dipus oegyptius*) from North Africa, presented by Mrs. R. Gurney; a Barn Owl (*Strix flammea*), British, presented by Lady Hutt; a Leopardine Snake (*Coluber leopardinus*), a Tesselated Snake (*Tropidonotus tessellatus*), European, presented by Mr. W. J. Wintle; a Grey-cheeked Mangabey (*Cercocebus albigena*, ♂), a Sooty Mangabey (*Cercocebus fuliginosus*, ♀) from West Africa, a Moustache Tamarin (*Midas mystax*) from the Upper Amazons, a Yellowish Capuchin (*Cebus flavescens*) from South America, two Tenrecs (*Centetes ecaudatus*), a Short-nosed Tenrec (*Ericulus setosus*), a Long-nosed Tenrec (*Hemicentetes semispinosus*) from Madagascar, a Festive Amazon (*Chrysotis festiva*) from Guiana, two Tui Parrakeets (*Brotogerys tui*), a Hawk-headed Parrot (*Deroptyus accipitrinus*) from Brazil, deposited; two Grey Squirrels (*Sciurus griseus*, var.) from North America, purchased; a Bosch-bok (*Tragelaphus sylvaticus*, ♂), eight Mocassin Snakes (*Tropidonotus fasciatus*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

OBSERVATIONS OF THE INFRA-RED SPECTRUM OF THE SOLAR CORONA.—In a recent issue of the *Comptes rendus* (vol. cxxxi. pp. 658-661), M. Deslandres describes some of his latest experiments in connection with the detection of the solar corona at ordinary times without the intervention of an eclipse. All the methods adopted prior to 1894 had been modifications of spectroscopic examination, using either the visual or ultra-violet rays, and were probably unsuccessful owing to the great proportion of these radiations existing in our general sky illumination, thereby diluting the small direct coronal light. In 1894 M. Deslandres found evidence that the sky radiation was very poor in the infra-red region, while the corona emitted this light abundantly, and this has since been investigated by Prof. Hale, in 1895, without producing any confirmatory results. M. Deslandres here suggests, however, that this non-success may have been due to those experiments having been made near the period of maximum sun-spot activity, at which time the corona is much more uniformly distributed round the limb than at periods of minimum.

During the last eclipse, in May 1900, the author, in conjunction with M. Charbonneaux, found that the infra-red coronal radiation was some one-half or one-third the radiation of the same part of the sky after the eclipse, and the work has since been continued daily at the Observatory of Meudon with the same apparatus. This consists of a mirror 0·30 metre aperture and 1·50 metres focus, a slit spectroscope with crown lenses and prisms, a sensitive Melloni or Rubens thermopile, and a very sensitive Deprez-d'Arsonval galvanometer. The slit of the spectroscope was 12 mm. long and 1 mm. wide, the prism train being so arranged that the thermopile only received the infra-red radiation from $\lambda 1\mu$ to $\lambda 1\mu{\cdot}8$. The slit has also been replaced by circular apertures 0 4 mm. and 1 mm. diameter.

The interesting conclusion is that, at all times of the day, the sum of the deviations along the equatorial region has always been greater than the corresponding sum of the readings in a polar direction. As it is improbable that the diffuse heat of our atmosphere would be unequally distributed over the small area corresponding to the angular diameter of the sun, this difference can only be attributed to the effect of the corona; the present time being a minumum of spots, the greater action along the equatorial region is in agreement with the known conspicuous equatorial extensions of the coronal streamers and the comparatively small polar plumes. Many variations in the disposition of the apparatus have been made to discover any possible systematic errors, but the results have throughout remained the same.

In contrast with the above report should be considered the preliminary statement of the results obtained by the expedition organised by Prof. S. P. Langley from the Smithsonian Institution during the same eclipse (*Astrophysical Journal*, vol. xii. pp. 69-76). The light given from a 17 inch siderostat mirror passed to a concave speculum 50 cm. diameter and 1 metre focus. Arrangements were made whereby either the full image of a part of the solar surroundings could be allowed to fall on the bolometer strip, or the light previously passed through a prism, thus sifting out any particular radiation for action on the bolometer.

Settings on the inner corona gave a distinct *negative* deflection with respect to the zero of the instrument, but this was numerically less than the deflection given by a setting on the centre of the dark moon; this shows that the coronal radiations were recognised by the bolometer, giving some 5 mm. deflection greater than that of the dark moon.

The fact of the negative deflection, however, indicates that the radiation reflected by the earth's atmosphere during the partial phase is vastly more intense than that of the corona. Also "the corona is effectively cooler than the bolometer, and appears, therefore, neither to reflect much light from the sun, nor, chiefly by virtue of a high temperature, to give light of its own, but seems rather to be giving light in a manner *not associated with a high temperature*, or at least with the preponderance of infra-red rays usual in the spectra of hot bodies."

ANNUAL REPORT OF THE MELBOURNE OBSERVATORY.—In the thirty-fourth annual report of the Melbourne Observatory, Mr. P. Baracchi, the acting Government astronomer of Victoria, summarises the work accomplished at the institution during the period March 1, 1899, to March 31, 1900. With the 8-inch transit circle the total number of right ascension observations was 3311, and of north polar distance 2406. Of the latter, 1435 were on stars selected from the astrophotographic catalogue plates, to serve as fundamental stars for the reduction of these plates. 786 observations of heliometer stars were made at the request of Dr. Gill, and have been sent to him for comparison. The computations for the third Melbourne General Catalogue of 3100 stars are about two-thirds completed. The astrographic work has made considerable progress, the two series of catalogue plates and the series of chart plates with single exposure of one hour having been completed with the exception of a few scattered regions. Catalogue plates for regions above 80° of declination are being duplicated, and the second series of chart plates, with triple exposure of 30 minutes each, has been commenced, giving three images of each star about 8″ apart. The measurements of the catalogue plates taken at this observatory and the Sydney Observatory have been made at Melbourne, and the progress made is stated in a joint report by Messrs. H. C. Russell and P. Baracchi. The first twelve months of the existence of the measuring bureau (commencing November, 1898) were occupied in preliminary instrumental experiments and training of observers, but during the last four months systematic measurement has been carried on Several new micrometers have been obtained, one by Repsold, similar to that used by Dr. Gill at the Cape. This has double slides, and thereby permits quicker measurements. At present two observers, relieving each other for alternate periods of one hour, measure in a day about 500 stars with the Repsold and about 400 with the local micrometer. As the total number of stars on the Sydney and Melbourne plates is probably 1,500,000, it is estimated that with three efficient measuring machines, and six observers employed from six to seven hours daily, the whole may be accomplished in some six or seven years. The photoheliograph, great telescope

and other equatorials have only been used on special occasions and for visitors, 594 of whom inspected the observatory during the year.

The automatic photographic registration of terrestrial magnetism was obtained with only 34 hours interruption during the year; absolute measurements were made on seven occasions, and instrumental constants, &c. determined.

The series of cloud photographs has been continued, 77 additional pairs of plates being taken from the roof of Parliament House and the observatory grounds respectively. These are now being measured and discussed in connection with visual observations.

ABNORMAL STARS IN CLUSTERS.—Prof. E. E. Barnard has for some time been engaged in micrometrical determinations of the positions of a number of the individual stars in the great globular clusters M 3, M 5, M 13, M 15, and M 92, and in the course of the work has noticed several peculiarities, the most striking of which is the fact that some of the stars in these clusters shine with a much *bluer* light than the majority of their neighbours, thus producing a remarkable difference between their photographic and visual magnitudes. So striking is this that the images in some cases are so large as to suggest variability (*Astrophysical Journal*, vol. xii., pp. 176—181). Comparisons have been made with a negative enlarged four times from an original of M 13 Herculis, taken with the Potsdam 13-inch photographic refractor in 1891.

The two stars, Nos. 148 and 131 of Scheiner's catalogue of this cluster are practically equally bright to the eye as seen in the sky; but on the photograph No. 148 has an image four or five times larger than No. 131.

Other neighbouring stars, however, register photographically the same relative brightness as determined visually. This led to the minute examination of No. 148 with high magnifying power, when it gave the impression of some object less sharp than stars near it, suggesting the idea of a small planetary nebula. Other stars showing the same abnormal features are detailed, and a numbered sketch of a portion of the cluster given for identification.

Prof. Barnard says he has found similar cases in other clusters, *e.g.* M 5 Libræ. A suggestion by Prof. Hale that a photograph taken through a yellow screen should not show these peculiarities was tested on the 40-inch Yerkes refractor and proved correct, the stars previously mentioned coming out on the photograph with almost the identical relative brightness they show visually in the same telescope.

The suggestion is made that these stars are of similar nature to the condensation or nucleus of the annular nebula in Lyra, perhaps bearing the same relation to the other stars of the cluster that the nucleus of that nebula does to the ordinary stars of the sky. It would appear, therefore, that the possibility of these abnormal stars being of the nature of nebulæ brings up again the question of nebulosity in the globular clusters.

RECENT STUDIES OF INFRA-RED REGION OF SOLAR SPECTRUM.—In the current issue of the *Comptes rendus* (vol. cxxxi. pp. 734–736), Prof. S. P. Langley describes the result of his recent work on the bolometric study of the solar spectrum in the infra-red. At the date of his last communication to the French Academy, in 1894, the knowledge of the region beyond $\lambda = 1\mu$ was very imperfect, but now, thanks to the great improvement of his bolometer, which is capable of detecting a variation of temperature as minute as the millionth part of a degree, the map of the calorific rays has been carried to $\lambda = 5{\cdot}8\mu$. The article is illustrated by a heliogravure of the calorific spectrum from $\lambda = 0{\cdot}76\mu$ to $\lambda = 5{\cdot}3\mu$, both the galvanometer record and the "line" integration being given. More than 600 lines are recorded, each of which has been studied separately and obtained by from six to twenty independent observations. Prof. Langley calls special attention to the observations of the *telluric* infra-red spectra, which have been studied during all seasons from 1895–1900. Systematic variations have been observed in them which appear to have some relation to the season in which they occur, and, although small, are very distinct.

THE ZODIACAL LIGHT.—*The Observatory* for November contains the first part of an article giving in a concise form the complete history of the zodiacal light. In this number the history is brought up to the year 1855, being derived mainly from two sources; (1) the article by M. E. Lefébure in *Ciel et Terre*, April, 1894; (2) a Review by Prof. C. E. Brame in the *Popular Science Monthly*, October, 1877.

THE NAPLES ZOOLOGICAL STATION.[1]

THE Zoological Station at Naples is so well known, either by personal experience or by repute, to zoologists the world over, that it may seem to some that any further account of it is quite unnecessary. But the institution has lately extended its scope and increased its equipment so as to appeal to workers in other lines of biology; and, moreover, as certain Associations and Universities in this country and elsewhere give annual grants towards defraying the expenses of special researches at Naples, it is due to scientific men in general that they should be kept informed from time to time of the conditions under which such work is carried on.

About ten years ago the then chairman of the British Association Naples Committee visited Naples, and gave an interesting report (NATURE, February 1891, p. 392) on the condition of the Zoological Station, in which he dwelt mainly upon the history, constitution, finance and publications; it will, therefore, be best that I should now draw attention chiefly to the present facilities for work at this world-renowned laboratory, and to the additions and improvements effected during the last decade. I am indebted to Prof. Dr. Anton Dohrn, the director, and to the secretary, Mr. Linden, for much information given me during my recent visit.

Since Dr. Sclater's visit in 1890 additional accommodation has been obtained by a re-arrangement of the roof of the main building. This gives space for a second laboratory, a supplementary library, and various smaller rooms used as chemical and physiological laboratories, for photography and bacteriology. A good deal of the research in recent years, both on the part of those occupying tables and of the permanent staff, has been in the direction of comparative physiology, experimental embryology, and the bacteriology of sea-water, and all necessary facilities for such work are now provided.

The number of work-places, in some cases separate rooms, known technically as "tables," is about fifty-five, and of these about thirty-four are rented annually by States, Universities, or Associations. Germany takes about ten of these, and Italy seven. There are three American tables, and three English (rented by the Universities of Cambridge and Oxford and the British Association respectively); consequently there are generally about half a dozen English and American biologists at work in the station; but Dr. Dohrn interprets in a most liberal spirit the rules as to the occupancy of a table, and, as a matter of fact, during my recent visit there were, for a short time, no less than three of us occupying simultaneously the British Association "table," and provided with separate rooms.

A work-table is really a small laboratory fitted up with all that is necessary for ordinary biological research, and additional apparatus and reagents can be obtained as required. The investigator is supposed to bring his own microscope and dissecting instruments, but is supplied with alcohol, acids, stains, and other chemicals, glass dishes and bottles of various kinds and sizes, drawing materials and mounting reagents. Requisition forms are placed beside the worker on which to notify his wishes in regard to material or reagents, he is visited at frequent intervals by members of the staff, and all wants are supplied in the most perfect manner. The recent addition of carefully planned filter-beds, by means of which half the sea-water in circulation in the tanks can be filtered and separated from the rest, has materially increased the facilities for some classes of experimental work.

The staff of the station consists of:—

(1) Dr. Anton Dohrn, the founder and director.

(2) Seven or eight scientific assistants—viz. Dr. Eisig, administrator of the laboratories; Dr. Paul Mayer, editor of the publications; Dr. Giesbrecht, assistant editor and supervisor of plates; Dr. Gast, assistant editor and supervisor of microscopic drawings; Dr. Schöbel, librarian; Dr. Lo Bianco, administrator of fisheries and préparateur; Dr. Hollandt, temporarily in charge of the microscopic sections department—all of them well-known men, each eminent in his own line of investigation. The post of assistant in the physiological department, formerly held by the late Dr. Schoenlein, is now vacant.

(3) In addition to the foregoing there are:—The secretary, Mr. Linden; two artists and the engineer.

(4) Also about thirty attendants, collectors and others em-

[1] Abridged from the "Note by the Chairman" of the Naples Committee in the report presented to the British Association at Bradford, September 1900.

ployed in the laboratories, in the collecting and preserving departments, aquarium and elsewhere.

This seems at the first thought a very large staff, but the activities of the institution are most varied and far-reaching, and everything that is undertaken is carried to a high standard of perfection. Whether it be in the exposition of living animals to the public in the wonderful tanks of the "Acquario," in the collection and preparation of choice specimens for Museums, in the supply of laboratory material and mounted microscopic objects to Universities, in the facilities afforded for research, or in the educational influence and inspiration which all young workers in the laboratory feel—in each and all of these directions the Naples station has a world-wide renown. And the best proof of this reputation for excellence is seen in the long list of biologists from all civilised countries who year after year obtain material from the station or enrol as workers in the laboratory. Close on 1200 naturalists have now since the opening of the Zoological Station in 1873 occupied work-tables, and as these men have come from and gone back to practically all the important laboratories of Europe and America, from St. Petersburg to Madrid, and from California to Japan, Naples may fairly claim to have been for the last quarter of a century a great international meeting-ground of biologists, and to have exercised a stimulating and co-ordinating influence upon biological research which it would be difficult to over-estimate.

The opportunities for taking part in collecting expeditions at sea are most valuable to the young naturalist. Dredging, plankton-collection and fishing are carried on daily in the Bay of Naples by means of the two little steamers belonging to the station, and a flotilla of fishing and other smaller boats. Many of the Neapolitan fishermen are more or less in the employ of the station, or bring in such specimens as they find in their work. The collecting organisation, under the charge of Dr. Lo Bianco, is now sufficient to provide from fifty to sixty workers at a time with all the material requisite for their varied researches.

But although the work of the Naples Zoological Station is thus many-sided, the leading idea is certainly original research. An investigator goes to Naples to make some particular discovery, and he goes there because he knows he will find material, facilities and environment such as exist nowhere else in the same favourable combination. The British Association Committee consider it most important that these opportunities for research should be open to British biologists in the future as they have been in the past, and it is on this ground that they confidently recommend the policy of sending selected investigators to Naples each year—a practice which has led to such satisfactory results in the past, and is full of promise for the future.

W. A. HERDMAN.

THE BRADFORD MUNICIPAL TECHNICAL COLLEGE.

DURING the recent Bradford meeting of the British Association many members availed themselves of the opportunity of inspecting the splendid Technical College which commenced a new era under the auspices of the Municipal Council twelve months ago. A description of the organisation of the college, and the work of its various departments, is given in the current number of *The Record of Technical and Secondary Education*, from which source, and the *Bradford Observer*, the following particulars have been derived. We are indebted to the Editor of the *Record* and to Mr. J. Nutter, secretary of the school, for the accompanying illustrations.

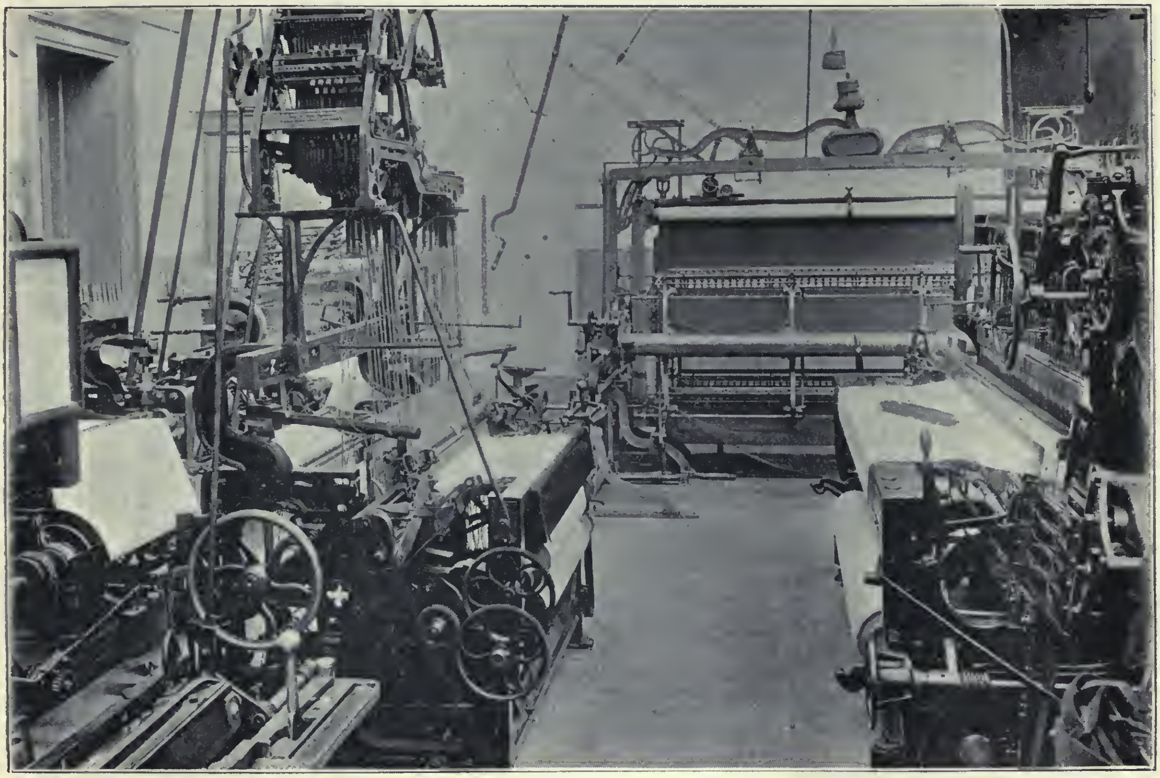

FIG. 1—Department of Textile Industries, Bradford Municipal Technical College—power loom shed, showing dress goods and coating looms and embroidery frame.

The management of the college is now in the hands of the Technical Instruction Committee of the Bradford City Council, and the scheme defining the objects of the college is as follows:—"The general object of the foundation shall be the maintenance of a technical college under the Technical Instruction Acts for persons above 14 years of age, subject to the provision that no secondary day school or school of science shall be carried on in the college, but that day and evening classes may be held in the subjects of art, and of manual, scientific or technical instruction connected with the trades and manufactures of Bradford and the neighbourhood, to which none shall be admitted under the age of 15 years, except on the recommendation of the governing body of

the school in which they have been taught, and in no case under the age of 14 years; in advanced commercial subjects at day and evening classes, to which none shall be admitted under the age of 16 years."

Department of Textile Industries.

In the textile industries department, which is directed by Mr. A. F. Barker, the idea that a satisfactory knowledge of the subject can be gained at evening classes has been given up as fallacious. A three years' course of study for day students has been mapped out, and students who enter must take at least two years of the course, though it is preferable that the whole should be gone through. In addition, a one-year course of textile-mechanics has been arranged, and a special textile and dyeing course is also available for those who desire to carry their studies still further. Such evening classes as have been arranged are all specialised courses for the benefit of those who, having passed through the day classes, are now engaged in the textile trade. In the day classes the teaching of the subject is subservient to the training of the student: in the evening classes means are afforded the already well-grounded student for gaining all possible up-to-date knowledge of his particular branch of the trade. One item in the arrangements deserves special mention, as it is an anticipation of the great development which will eventually take place. Lectures on the preparation of wool and its treatment until it reaches the yarn stage are included in the three years' day course, and for the evenings a course of twenty-five lectures by acknowledged experts in the various branches has been arranged. This is in preparation for the carrying out of the full plan of the committee to remodel the textile industries department by providing plant for the practical teaching of the whole of the operations involved in the production of cloth from the raw material. The Clothworkers' Company have recently carried out a similar scheme at the Yorkshire College. The idea, which as far as possible will be worked to, in providing new buildings and machinery, is to make the college a model factory in which, subject to obvious limitations, work will be carried out on an economical and commercial scale. In the "model factory" each department would balance the other. For instance, there would be a sufficiency of spinning frames to supply the necessary yarn to the looms, and so on throughout. Many important advantages would follow such a scheme. It would add interest to the work, and the students, in addition to gaining skill in the various operations and knowledge of the scientific laws which govern them, would also get an insight into mill management, a practical acquaintance with manufacturers' book-keeping, and a grasp of the economic problems involved.

Department of Chemistry and Dyeing.

Mr. W. M. Gardner is in charge of this department. In addition to the work in the chemical laboratories and experimental dyehouse, it is intended that in the future a practical dyehouse, fitted with typical machinery—including finishing machines—shall be provided, in which the students may be introduced to practical work. An experimental dyehouse for trade research work will also be an important feature in the future. The complete course in chemistry and dyeing occupies three years. The first year's work consists largely of chemistry and physics; the second includes chemistry, but dyeing is specially studied; and in the third year the work is to be still more specialised, and the students will be engaged during a part of their time in the dyeworks of the city. The course is made as complete as possible by the inclusion of physics (with special reference to chemical questions and to colour) and engineering (with special reference to dyeworks machinery). The work of this department in the future, and especially when the new buildings are available, will cover a much wider field than the dyeing trade, and will deal with all the chemical industries of the neighbourhood, but the same principle will operate, and every new branch that is opened and every fresh class that is started will have a direct bearing upon some local industry. Some of the new lines of work are supplementary to the other departments. Thus, teaching in bacteriology forms part of the

FIG. 2.—Dyehouse of the Department of Chemistry and Dyeing, Bradford Municipal Technical College.

civil and sanitary engineering classes, and metallurgy—for which a laboratory is to be built and a lecturer appointed—will be taken by mechanical engineering students. Botany, biology and microscopy are sciences which have a direct bearing on many of Bradford's industries, and they have also been taken up. The evening classes consist of specialised courses in chemistry and dyeing for advanced students and persons already engaged in trade.

Engineering Department.

The work of the engineering department, which is under Mr. G. F. Charnock, is divided into four sections, viz. (1) civil engineering, (2) mechanical engineering, (3) electrical engineering, and (4) building trades and architecture, the last named being in conjunction with the art department. Some much-needed additions to the machinery are to be made. Several new machine tools have been ordered, and, as opportunity offers, it is intended to substitute the newest examples for all machines of an old-fashioned type. The new syllabus in civil engineering has been framed to meet the requirements of the various professional bodies. A special feature is to be made of sanitary work, and some attention, including laboratory work, will be given to the new methods of sewage treatment. The mechanical engineering department has an increasingly important part to play in the industrial life of Bradford, and by no means the least important part of the work of this department will be to assist in training up a class of men suitable for the position of power superintendent in mills and factories. In the development of new ideas the department has also its place. The systematic study of mechanism and the method of designing mechanical motions would enable many a good idea which would otherwise be lost to its inventor to be worked out to a successful issue. Almost every technical school of any note on the Continent and in America has its collection of models systematically arranged to lead up from the simplest motions to the most complicated contrivances, but Bradford as yet can give the inventor no such aid.

Arrangements have been made for the proper teaching of electrical engineering, and a laboratory has been fitted up for practical work.

A room has also been reserved as a mathematical laboratory, and is fitted with apparatus and models to render the teaching as concrete as possible. Special attention is given to the slide rule, and there is a useful collection of measuring instruments. A calculating machine and other similar apparatus have also been provided.

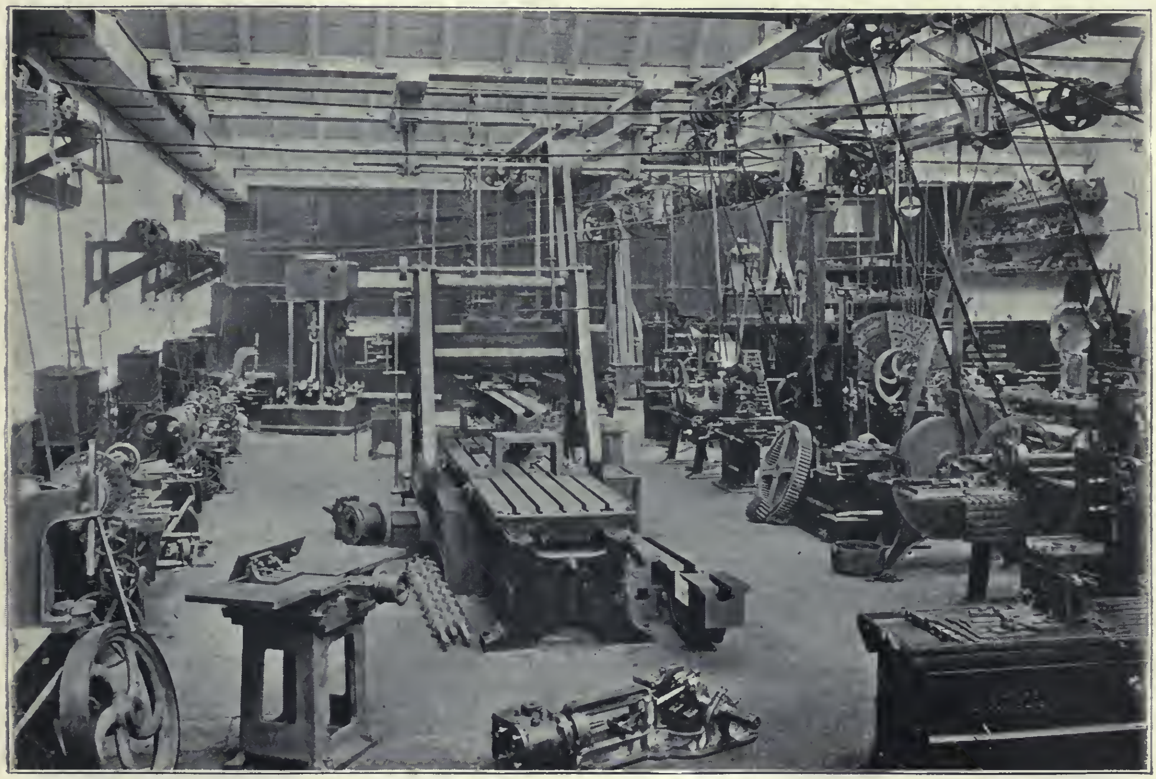

FIG. 3.—Workshop of the Department of Civil and Mechanical Engineering, Bradford Municipal Technical College.

A SUSPENDED RAILWAY.

THE curious railway represented in the accompanying illustration from *La Nature* runs from Vohwinkel to Barmen, through Elberfeld, along the Wupper Valley, in Rhenish Prussia. It is now working regularly, and was to have been formally opened recently by the Emperor of Germany, but the ceremony was postponed on account of the illness of the Empress Frederick. Brief descriptions of the railway have been given in several periodicals, and an illustrated account appears in the October number of the *English Illustrated Magazine*, from which some of the following particulars have been derived.

The total length of the railway is about 8¼ miles, of which more than three-quarters is over the river Wupper. The railway is supported above the river on A-shaped trestles, with the sides rising from each bank, and are placed at intervals of 30 metres. In the highway, along the roads, the supports take the form of an inverted U. The lower part of the latticed girders at the top of the supports contains the rail from which the carriages are suspended. Upon the upper face of this rail runs a two-wheeled truck or trolley containing the electric motors. Two of these trucks, placed nearly thirty feet apart, are supplied to each carriage. From each truck a heavy hook, fastened to the roof of the carriage, projects round the rail, as

shown in Fig. 1. Although the trolley runs on a single rail, it is prevented from falling over by the hook, and also by the fact that the centre of gravity is immediately below the wheels. The railway is a double track, one line for the up and the other for the down trains.

The curve of the track has an average radius of 90 metres; at Vohwinkel, however, there is a curve with a radius of 30 metres, and in one place the radius of curvature is much less than this. At each terminus of the line the track is built in the shape of a large loop, so that the arriving carriages may pass round to the departure platforms. The inclines are slight, the greatest gradient being 4·5 in 100.

The cars are propelled electrically, by current conveyed by means of a sliding contact from generating stations to motors on the trucks supporting the cars. Each truck has a motor of 30 horse-power, and works at a pressure of 600 volts. The cars themselves are about thirty feet long and are of the corridor pattern. There are two cars to a train, and each can carry fifty passengers. No less than nineteen stations are provided in the length of eight miles traversed by the line, and the trains succeed one another every two or three minutes.

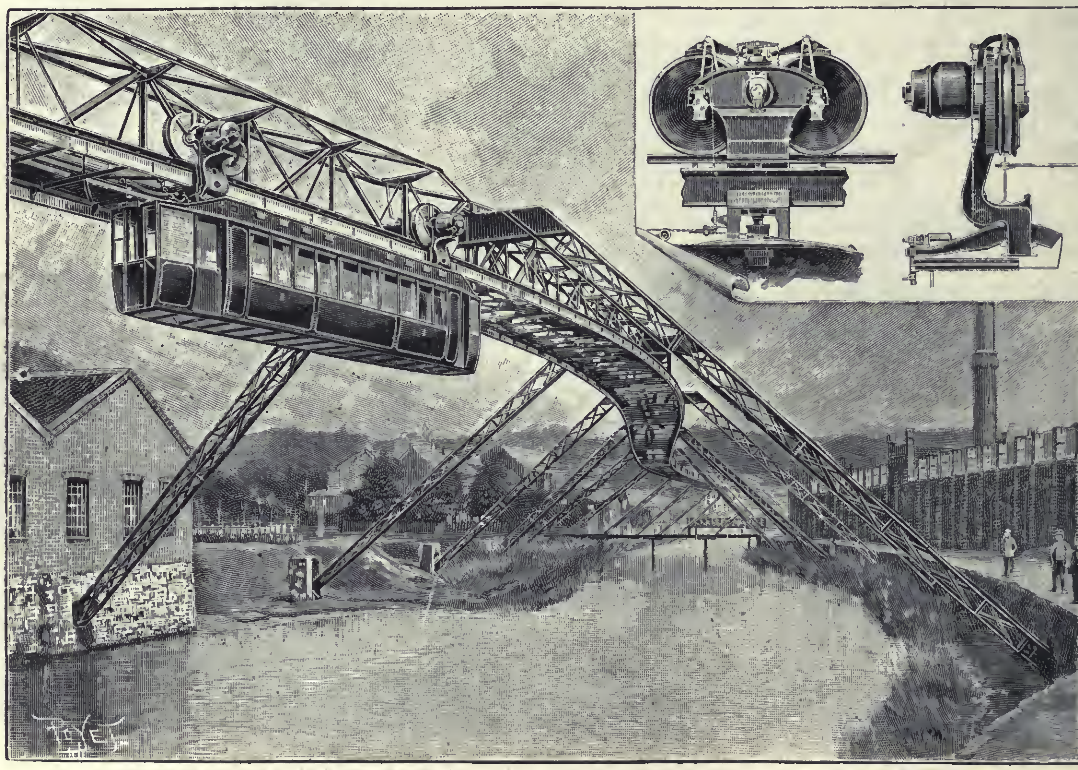

FIG. 1.—General view of a part of the Wupper Valley Railway at Elberfeld. The system of suspension of the trucks is shown in the small figure.

Each car is fitted with a Westinghouse pneumatic brake, a hand brake and an electrical brake, so that it is well under control. The cost of the railway, comprising stations, permanent way, and rolling stock, is stated to have been 56,000*l.* per mile. The proprietor of the railway was Herr Eugene Langen, of Cologne, who died before the line was completed.

OUTPUT AND VALUE OF BRITISH MINERALS.[1]

THE most striking fact recorded in the mineral statistics for 1899 is the enormous output of coal, viz., 220,094,781 tons, showing an increase of 18,040,265 tons compared with the previous year. This country is now producing twice as much coal as it did in 1870, and probably nearly four times as much as in 1850. Durham and Yorkshire together are now yielding about as much coal as the whole of the United Kingdom half a century ago.

The unsatisfactory part of the particulars is the deficiency of detail concerning our most important minerals, coal and iron ore. County outputs are given, but no further descent into local details is permissible, because the Coal Mines Regulation Act prohibits the publication of the individual annual returns. While a statement is made of the output of every little lead or tin mine, it is impossible to state officially which of our colliery companies can be compared, for instance, with such great undertakings as those at Anzin and Lens on the other side of the Channel. Is it wise that no particulars should be kept of the gradual depletion of our great national treasure? The total yearly shrinkage is recorded, but no account is kept in our official statistics of each individual vault which is being drained of its riches.

The Mineral Statistics Committee in 1894 recommended the amendment of the Statute and the publication of the output of individual collieries, but at present nothing has been done. The anomaly involved in the present state of things is specially marked in the case of our iron ores. The law prohibits the publication of the returns of *stratified* ironstone, but allows it in the case of *unstratified* iron ore. Consequently, full details are given of the amount of ore produced by each iron mine in Cumberland, whilst information concerning the output of individual mines in the Cleveland district has to be withheld from publication.

Apart, however, from the question of the production of individual mines, the total output for the year, amounting to more than 220 million of tons and showing an increase of about 9 per cent. on the output for the previous year, points to the urgency which the question of the exhaustion of the coal supply is rapidly assuming. While it is impossible, in an annual report on the mineral output, to undertake the task of estimating the amount of coal still remaining in the British Isles, and of attempting to arrive at any conclusion as to the time that may elapse before its exhaustion begins to be felt, it may perhaps not be out of place to call attention to the practical importance of

[1] Reprinted from a report by Prof. Le Neve Foster, F.R.S., on the output and value of the minerals raised in the United Kingdom in 1899, the amount and value of the metals produced, and the exports and imports of minerals. Published by the Home Office.

checking its present thriftless use. Prof. Perry pointed out a few weeks ago to the members of the British Association for the Advancement of Science that the best steam engines are utilising only one-twelfth of the energy available by the combustion of the fuel, while the ordinary steam engines utilise a far less proportion. Whether our coal supply is sufficient to last for some centuries, or whether, as is the opinion of many competent authorities, a serious coal famine will begin to be felt within the lives of the present generation, economy in the use of coal is unquestionably of the utmost importance, and the investigation of the best means of effecting such economy would repay even a large expenditure, whether by the Government or by industrial corporations and technical societies. If the result of such inquiry were merely to effect an economy of one per cent. in the consumption of coal this would mean an annual saving to the coal consumers of this country of nearly $1\frac{3}{4}$ million tons, worth at last year's prices about £625,000.

Such an investigation might also deal specially with the question of the supply of coal for the Navy. At present certain classes of coal, which with little or no effort on the part of the stoker can be burned without the production of smoke, are specially used for steamships and are often known by the name of "steam coal." If any means can be devised, by investigation and experiment, by which other classes of coal can be burned smokelessly, as is surely possible, our ships will no longer be dependent upon one class of fuel, the naval coal bills will be lessened, and the danger of the failure of coal available for naval purposes will arise only when the total coal supply of the country approaches the point of exhaustion.

Another matter of interest in the present statistics is the increase of the exportation of coal. The quantity of coal exported in 1899 (exclusive of coke and patent fuel) was more than 41 million tons—an amount more than the whole output of coal in any country in the world except the United States and Germany. Of this export more than three-sevenths in quantity and almost half in value is from the South Wales ports. In 1898 and also in 1897 the export was only a little over 35 millions. For the purpose of comparison it is better to take the year 1897, as the quantities dealt with in 1898 were disturbed by the coal strike. Compared with the former year there has been an increase of nearly 6 millions in the total export, and this increase is almost entirely in the export to foreign countries, the export to the British Colonies and Possessions having increased by only 200,000 tons. The countries whose purchases of coal show the largest increase are Russia (which has increased its purchase by nearly $1\frac{1}{2}$ millions), France (more than 1 million), Sweden ($\frac{3}{4}$ million), Italy and Holland. The exports to Germany, Spain, Egypt and South America show only a small increase. The export to the United States is inconsiderable, amounting only to 119,000 tons, chiefly to ports on the Pacific. Among the British Colonies and Possessions there is a considerable increase in the export to India, and some increase in that to South Africa; elsewhere the tendency is rather to decrease.

It must not be assumed that the whole of the coal exported to foreign countries was consumed by foreign nations. Some of it was merely shipped to foreign ports and there utilised for recoaling English steamers. What proportion was so employed does not appear from any statistics that are available, though possibly some indication may be gathered from the amounts sent to Malta, Gibraltar, and Aden, whieh in 1899 were respectively 418,000, 326,000, and 176,000 tons.

As regards minerals other than coal, the increasing importance of aluminium may be noted. The output of this metal now amounts to 550 tons, with a value of 71,125*l*. The output thus approaches in quantity nearly to that of copper, while the value is considerably greater. In spite of higher prices, copper, lead and tin show diminished outputs.

The total value of all minerals raised approaches 100,000,000*l*. sterling, the increase of 20,000,000*l*. compared with 1898 being mainly due to the enhanced value of coal. With our present output, a rise of one penny in the price of coal represents nearly one million of money.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An election to an Isaac Newton Studentship in astronomy and astronomical physics will be held next term. The studentship is worth 200*l*. a year for three years. Candidates must be Bachelors of Arts who are under twenty-five on January 1, 1900.

Mr. H. F. Baker, F.R.S., of St. John's College, has been appointed University Lecturer in Mathematics.

At the biennial election to the Council of the Senate on November 7, the following new members were returned: Dr. Ryle, Dr. Taylor, Prof. Ridgeway, Mr. R. F. Scott, St. John's.

Science states that a bronze medallion with a likeness of Prof. Sylvester will hereafter be awarded as a mathematical prize at the Johns Hopkins University.

DR. LORENZ, of the University at Halle, has been made director of the physical and technological institute of the University of Göttingen.

THE following appointments have recently been made at University College, Sheffield. Dr. S. R. Milner, late junior demonstrator in physics at Owens College, to be demonstrator and assistant lecturer in physics. Dr. T. S. Price to be additional demonstrator in chemistry.

MR. E. J RUSSELL, assistant lecturer and demonstrator at the Owens College, has been appointed lecturer in chemistry at the South-Eastern Agricultural College in succession to Mr. H. H. Cousins, who has been appointed agricultural chemist to the Government of Jamaica.

CALENDARS of University Colleges are all built upon much the same pattern, but each has some noteworthy characteristics. For instance, we see that the Durham College of Science, Newcastle-upon-Tyne, like one or two similar institutions, has a marine biological laboratory available for its students at Cullercoats. The agricultural department has been well organised, and is entrusted with the scientific direction of the farm acquired for the purpose of demonstration and experiment by the County Council of Northumberland. Opportunity is afforded to qualified students to undertake original work in all departments, and the students are permitted to visit chemical and other works in the district. Prof. Louis is to deliver a special course this session for the instruction of persons proceeding to any of the gold-fields. The course will deal with prospecting for gold, the methods of extraction of gold from its ores, and the assaying of gold ore and bullion. A scheme is on foot for the establishment of a new northern university based on the Durham College, on the model of that founded at Birmingham upon Mason College.

A SCHEME of agricultural education, which Mr. A. N. Pearson has drawn up for Victoria, in connection with the Royal Commission on Technical Education, is founded on the principles which are now accepted to form the only permanent basis for scientific instruction: viz. that natural knowledge only comes by individual experience in the school of nature. Many elementary facts of agriculture lend themselves readily to educational purposes, and by employing them in a proper way it is possible to give young pupils an intelligent view of natural processes which will be of value in the practical work of later life. With a few seeds it is easy to study germination and the growth and structure of root and stem. Simple examinations of soils may follow, and then determinations of the composition of plants. After this, there would be but a short step to an elementary knowledge of the chemical composition of soils and of commercial plant foods, and the pupil could make intelligent use of the latter, either in growing pot plants, or in cultivating small garden plots. Mr. Pearson gives in his report a scheme for the education of youths in agricultural colleges and farm-schools, and he shows that he is inspired with the spirit of true education. By adopting such a scheme of work as he suggests, the Government of Victoria will show foresight for the future welfare of the colony, and will make its methods of agricultural instruction equal to the best.

FATHER A. L. CORTIE, S.J., discoursed on the teaching of science in Catholic Schools at the last conference of Catholic Colleges on Secondary Education; and his paper is given in full in the official report just received. The fundamental note of his remarks is that classics and mathematics ought to be the foundation of our educational structure, and the "finish and polish of a course of science" should be put upon it afterwards. It is suggested that scientific men wish to oust the classics, and substitute a merely commercial and scientific education as the mental training of the boy intended for trade and the practical walks of life. This, however, scarcely expresses the real state of the case, for many scientific men are familiar with classical literature and would be sorry to see it neglected. But can the same be said of classical men as a rule: are they inclined to give science a proper

place in their educational curricula? A glance at the Time Table of any Public School, and of most Grammar Schools, or at a list of scholarships available at Universities, will show that science is the Cinderella in secondary schools, and its presence is more tolerated than encouraged. When science (rationally taught, of course) takes so many hours of a boy's school work as classics, it will be time to suggest that the languages of ancient Greece and Rome are being ousted. Father Cortie's views as to the plan and method of science teaching may be judged from the final remarks from his paper:—"Our aim in teaching science, as in teaching every other subject to the boys committed to our charge, ought to be chiefly directed to training the mind, and not to the imparting of a number of isolated and disconnected facts. I would advocate in the first place a preliminary course of classical and literary training before joining the science classes, and secondly that in the science course itself the training should be neither wholly didactic, nor yet wholly experimental, or Heuristic, to employ the term so much in fashion at present, but a judicious mixture of both. A cultured mind should be the outcome of our training, in science, as in other subjects. And for true culture, a knowledge of facts, in lieu of knowledge of principles and methods, is worthless."

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, November 9.—Prof. A. W. Reinold, F.R.S., Vice-President, in the chair.—Dr. R. A. Lehfeldt read a paper on "Electro-motive force and osmotic pressure." This paper is an attempt to explain a difficulty in the interpretation of the ordinary logarithmic formula for the E.M.F. between a metal and solution, pointed out by the author at the Dover meeting of the British Association. An expression for the E.M.F. of a concentration cell is obtained thermo-dynamically upon the assumption that the electrolyte is only partially dissociated. A partition is used which is permeable to water but not to the salt or its ions, and the conclusion follows that the E.M.F. depends, not on the osmotic pressure of the metallic ions, but on that of the solution as a whole. A graphical representation is given plotting osmotic pressure against dilution, assuming Boyle's law to hold, and it is shown that the E.M.F. is not proportional to the integral $\int PdV$ but to the converse integral $\int VdP$. Assuming, further, that the osmotic pressure changes according to Van der Waals's equation, the E.M.F. is greater than that calculated from Boyle's Law. If the electrolytic solution pressure is calculated from the integral $\int PdV$ it comes out 10^{19} atmospheres; but if from the converse integral, the value obtained is about 20,000 atmospheres. A comparison between actual E.M.F.'s and those derived from the equation given by the author should afford, if the formula is correctly deduced from the assumptions made, a measure of how far the osmotic pressure deviates from that indicated by Boyle's law. Experiments upon concentration cells have been made by Helmholtz, Wright and Thomson, Moser, Lussana and Goodwin; but as their work was performed upon cells with migration of ions, the calculation of the osmotic pressure is rendered uncertain by the introduction of the transference ratio. Accordingly the author has measured the E.M.F.'s of cells without migration, using zinc as electrodes and chloride and sulphate of zinc as salts. The E.M.F. was measured by the compensation method, using a post office box through which a current was sent by an accumulator. The accumulator kept up a constant potential difference, and was standardised daily by means of a Clarke cell. The experimental results agree with the calculated over the range centi- to deci-normal, showing that the deviation from the value given by the logarithmic formula is accounted for by the incomplete dissociation of the salts. The osmotic pressures are then calculated from the E.M.F.'s and the values of PV plotted. They show irregularities due to the combined effect of the decreasing dissociation of the salt and the increasing departure from Boyle's Law. Dividing the product PV by Van 't Hoff's factor, determined from conductivity, values are obtained showing variations similar to those observed in the behaviour of gases when subjected to high pressure. Mr. Whetham said there was one form of membrane which is quite permeable to water and yet does not allow either salts or the ions to get through. He referred to the free surface of the solution itself. The water being volatile can get out, but the salt cannot. Dr. Donnan said the author seemed to have discovered things well known; for instance, the integral $\int VdP$ is generally taken as proportional to E.M.F. He expressed his interest in the explanation of the difficulty in the logarithmic formula. Dr. Lehfeldt, in reply, said Goodwin had used the integral $\int VdP$ but had not made any numerical calculations by means of it. —Mr. R. J. Sowter read a paper on "astigmatic lenses." An astigmatic lens is one which so acts on rays of light falling on it as to produce, in general, two focal lines in the refracted ray system. A lens derived from a quadric surface is the general elementary type of astigmatic lens, and in the paper an ellipsoidal lens is selected and considered. The focal lines are parallel to the elliptic axes, and correspond to the lens powers in these directions. These powers are proportional to the inverse squares of the axes. A curve drawn through all points on a lens where the material thickness is constant may be said to determine a natural aperture for that lens. A method of natural apertures is employed to establish the various relation set out in the paper. An ellipse is the natural aperture for an ellipsoidal lens, a circle for a spherical lens, and an infinitely long rectangle for a cylindrical lens. It is shown that two cylindrical lenses crossed at right angles are equivalent to an ellipsoidal lens, and the power of the combination in any direction is the same as that of the ellipsoidal lens in that direction. It is also shown that two obliquely crossed cylindrical lenses are equivalent to an ellipsoidal lens, or to two cylindrical lenses of definite powers crossed at right angles, or to a cylindrical and a spherical lens; for a spherical lens may be replaced by two equal cylindrical lenses crossed at right angles. Prof. S. P. Thompson said he had never seen the treatment of an ellipsoidal lens before, although the extreme case of a paraboloidal lens had been considered. The author's method was, as far as he knew, new, and would be very convenient to work with. Mr. A. Campbell then read the following papers:—(*a*) "On a phase-turning apparatus for use with electrostatic voltmeters." Electrostatic voltmeters are particularly insensitive at the lower parts of their ranges, the divisions closing in very much towards the zero point. When measurements of small direct-current potential differences have to be made, it is an easy matter to add to the voltage to be measured a constant voltage large enough to bring the deflection to an open part of the scale. If the small voltage to be measured is an alternating one, it is necessary that the auxiliary voltage should alternate with the same frequency, and be in phase with it. The apparatus described enables the phase of the auxiliary voltage to be turned until it agrees with the one to be measured. The phase difference referred to is not the time lag but the angle whose cosine is the power factor and may be called the power lag. The method is to get two independent equal voltages, U_1 and U_2, differing in power phase by $\frac{\pi}{2}$, and to add together suitable fractions of these, such as $U_1 \sin \phi$, $U_2 \cos \phi$. The resultant is equal to U_1, but with the power phase turned through ϕ. The unknown small voltage is connected in series with an auxiliary voltage and a voltmeter, and the phase of the latter voltage is turned until the maximum deflection is obtained. (*b*) "On a method of measuring power in alternating current circuits." The circuit in which the power is to be measured is connected in series across the supply circuit with a small non-inductive resistance. By means of a transformer the small voltage on this resistance may be transformed into one whose power phase is π behind the voltage on the resistance. This is added to the voltage on the circuit to be measured, and then reversed and added again. The difference of the squares of these effective resultants is shown to be equal to a constant into the power to be measured. If there is any direct current, it must be measured separately by a Weston voltmeter or other suitable instrument. (*c*) "Note on obtaining alternating currents and voltages in the same phase for fictitious loads." When testing instruments for the measurement of large amounts of electrical power or energy, it is usually desirable to do so by means of fictitious loads, or by applying to the instrument under test current and potential difference representing the required load. In order to obtain a fictitious non-inductive load with alternating currents, the potential difference and current should be in the same phase. The current for the

instrument under test is got by means of a transformer worked on a hundred volt circuit. The potential difference in the same phase is got by allowing the current to flow through a non-inductive resistance and increasing the voltage at the ends of the resistance to the required amount by means of another transformer.—The Society then adjourned until November 23.

Chemical Society, November 1.—Prof. Thorpe, President, in the chair.—The following papers were read:—Action of alkalis on nitro-compounds of the paraffin series. Part 2: The reactions and constitutions of methazonic acid and the formation of isoxazoles, by W. R. Dunstan and E. Goulding. On treating nitromethane with alkalis, a mono-basic acid, methazonic acid, $C_2H_4N_2O_3$, is produced; when heated with acids or alkalis it decomposes into carbon dioxide, hydrogen cyanide, and hydroxylamine. The authors attribute the constitution

```
         CH2.NH
          |   |
  HO.N:C—-O
          ||
          O
```

to methazonic acid.—Hexachlorides of benzonitrile, benzamide and benzoic acid, by F. E. Matthews. Chlorine water in presence of light converts benzonitrile into a crystalline hexachloride, $C_6H_5Cl_6.CN$, which, when heated with sulphuric acid at 170—180°, is converted into the hexachloride of benzamide; the latter is oxidised by fuming nitric acid yielding benzoic acid hexachloride, $C_6H_5Cl_6.COOH$.—The influence of solvents on the rotation of optically active compounds, 1, by T. S. Patterson. As the result of experimental work on ethyl tartrate, the author traces the variation of rotatory power with solvent to the variation of the asymmetry of the molecule owing to changes of the internal pressure in the solution.—The action of heat on ethyl sulphuric acid, by W. Ramsay and G. Rudorf. Ethyl hydrogen sulphate yields, when heated, sulphur dioxide, carbon dioxide, carbon monoxide and ethylene, as gaseous decomposition products.—Contributions to the knowledge of fluorescent substances: (1) The nitro-derivatives of fluorescein, by J. T. Hewitt and B. W. Perkins. Anhydrous dinitrofluorescein is not fluorescent in soda solution; the authors are unable to confirm von Baeyer's analytical numbers for tetranitrofluorescein, and suggest the composition $C_{20}H_{10}(NO_2)_4O_6$ for this substance.—Derivatives of ethyl α-methyl-β-phenylcyanglutarate, by W. Carter and W. T. Lawrence. Ethyl cinnamate and ethyl sodiocyanacetate interact in alcoholic solution and, on adding methyl iodide to the product, the two stereoisomeric forms of ethyl α-methyl-β-phenyl-α-cyanglutarate are produced; derivatives of these substances are described.—The nitration of acetamino-orthophenyl acetate (diacetylorthoaminophenol). A correction, by R. Meldola and E. Wechsler.—Rhamnazin and rhamnetin, by A. G. Perkin and J. R. Allison. The authors show that rhamnazin is a methoxyrhamnetin and that rhamnetin has the following constitution:—

```
CH3O.C—CH=C.CO—--C——C—-CH:C.OH
      ||     |      ||   ||     |
   HC.C(OH):C.C(CO).C.OHCH.CH:C.OH.
```

—Luteolin, 3, by A. G. Perkin and L. H. Horsfall.—Genistein, 2, by A. G. Perkin and L. H. Horsfall.—The colouring matter of the flowers of *Delphinium consolida*, by A. G. Perkin and E. J. Wilkinson. The yellow colouring matter in these flowers is present as a glucoside, and has the composition $C_{15}H_{10}C_6$; it yields phloroglucinol and p-hydroxybenzoic acid on fusion with potash.—Note on Gallinek's amidomethylnaphthimidazole, by R. Meldola and F. W. Streatfeild.—The amount of chlorine in rain-water collected at Cirencester, by E. Kinch.—Researches on the alkyl-substituted succinic acids: (3) Dissociation constants, by W. A. Bone and C. H. G. Sprankling. The authors have determined the dissociation constants of a number of new di-alkyl-substituted succinic acids, and show that as the mass of a normal alkyl-substituting group increases the dissociation constant also increases; in the case of 'iso' substituting radicles, however, there is a structural effect opposed to that of mass.—The reaction between ethyl alcohol and hydrochloric acid, by T. S. Price. The author has determined the velocity of reaction between ethyl alcohol aud hydrochloric acid, and finds that the velocity increases very rapidly with rise of temperature.

Royal Microscopical Society, October 17.—Mr. Carruthers, F.R.S., President, in the chair.—Dr. Hebb brought before the notice of the meeting samples of stains for microscopic specimens, prepared by Messrs. Burroughs, Wellcome and Co. The stains were in a solid form, each "soloid," as they are termed, containing a definite amount of the staining reagent. The advantages of this form of preparation are simplicity and economy.—Messrs. R. and J. Beck exhibited a new pattern students' microscope. It was of the continental form, and was chiefly noticeable for its cheapness, which was attained without sacrifice of quality by adopting an improved method of manufacture. It was called the "London" microscope, and had rack and pinion coarse adjustment, perfect micrometer screw fine adjustment, vulcanite top stage, iris diaphragm in sliding tube, and spiral substage fitting.—Mr. F. W. Watson Baker gave an exhibition of slides and models illustrating the structure and development of the skin.—The Secretary announced that Mr. Millett had forwarded Part ix. of his report on the Foraminifera of the Malay Archipelago, which would be taken as read; the paper appears in the current number of the *Journal* of the Society.

MANCHESTER.

Literary and Philosophical Society, October 16.—Prof. Horace Lamb, F.R.S., President, in the chair.—Prof. H. B. Dixon, F.R.S., gave a summary of the results of experiments, conducted by himself and Mr. F. W. Rixon, on the specific heat of gases at high temperatures. As part of a larger investigation, the authors have determined directly the specific heat of carbonic acid, up to 400° C., at constant volume. The gas is screwed up in a mild steel cylinder, which is heated in a gas-oven running on rails. The oven and cylinder can thus be brought quickly over the calorimeter, into which the cylinder falls through trap-doors forming the bottom of the oven. The transference is thus effected with a minimum loss of heat. The difficulties arising from splashing and from escape of steam are overcome by dropping the cylinder into a glass tube dipping some distance below the water. The glass tube breaks at a crack made in the neck, and thus ensures a complete immersion of the hot cylinder at a good depth in the water, which closes over the cylinder in a cataract. A similar experiment being performed with the empty cylinder, the difference gives the heating effect of the gas. The results given below for CO_2 show that the method, which, it is hoped, may yet be improved, is a workable one:

Initial temperature of gas	Final temperature	Mean	Specific heat
115	16	65·5	·200
192	16	104	·211
298	21	159·5	·288
398	21	209·5	·356

The authors are now measuring the specific heat of nitrogen in the same way.

PARIS.

Academy of Sciences, November 5.—M. Maurice Lévy in the chair.—On the velocity of light, by M. Perrotin. A redetermination of the velocity of light by Fizeau's method. The distance between the two stations was nearly 12 kilometres, and the mean result of about 1500 observations by two observers was 299,900 kilometres per second.—On the latest results obtained in the study of the infra-red part of the solar spectrum, by M. S. P. Langley. The author has been able to extend his previous researches on this subject in two directions, firstly by increasing the sensibility of the bolometer, and secondly by taking the observations at a great altitude, about 13,000 feet. By reason of the remarkable purity of the atmosphere at this height, a region of the spectrum has been discovered beyond the extreme point attained by previous observers. The tables now issued contain about 600 lines, 400 of which are new. The paper is accompanied by a whole page illustration.—Remarks on the preceeding communication, by M. J. Janssen. Attention is drawn to the effect of season upon the lines observed. By working at a high altitude some telluric lines may be eliminated.—On a class of algebraic surfaces, by MM. G. Castelnuovo and F. Enriques. On the topographical correction of pendulum observations, by M. J. Collet.—Acetals of polyvalent alcohols, by M. Marcel Delépine. Determinations of the heats of combustion of the formals and acetals of glycol, erythrol and mannitol.—Constitution of the nitro-derivatives of ethyl dimethylacrylate, by MM.

L. Bouveault and A. Wahl. The nitro-derivative previously described is split up by ammonia, giving acetone and ethyl nitro-acetate.—On the simultaneous presence of saccharose and gentianose in the fresh root of the gentian, by MM. Em. Bourquelot and H. Hérissey.—Note on a new glucoside extracted from the seeds of *Erysimum*, belonging to the Cruciferæ, by MM. Schlagenhauffen and Reeb. A description of the isolation, chemical and physiological properties of a new glucoside isolated from Erysimum, to which the name erysimine is given.—The distribution of the sexes in the eggs of pigeons, by M. L. Guènot. It is shown that the view commonly held concerning the distribution of the sexes in the two eggs of the pigeon is not supported by experiment, the relations found corresponding perfectly with those calculated from the law of chances.—Contributions to the study of the phenomena of metamorphosis in the Diptera, by M. C. Vaney.—Sexual reproduction in *Ophrycystis*, by M. Louis Léger.—On the parasitism of *Ximenia americana*, by M. Edouard Heckel.—On gaseous projectiles proposed for the prevention of hail, by MM. G. Gastine and V. Vermorel.

NEW SOUTH WALES.

Linnean Society, August 29.—The President, the Hon. James Norton, in the chair.—Descriptions of some new *Araneidae* of New South Wales, by W. J. Rainbow. This paper contains descriptions of four new species, and one well-marked variety of a previously described form. Of the forms described, one is referable to the genus *Dysdera*, Latr., and is consequently a new generic record for Australia. For this species the author proposes the name *D. australiensis*. Other forms described are *Tama eucalypti*, *Araneus parvulus*, *A. singularis*, and *Dicrostichus furcatus*, Camb., var. *distinctus*.—Studies on Australian Mollusca, Part ii., by C. Hedley. Several new marine shells from Queensland and New South Wales are described, including species of *Chlamys*, *Puncturella*, *Terebra*, *Leucotina* and *Liotia*. Two plates which accompany the article illustrate these, together with species named by Tenison-Woods, Brazier and Beddome, but not before figured. The genus *Menon* published in Part i. is shown to be reducible to *Chileutomia*, Tate and Cossmann, hitherto known only as an Eocene fossil. Notes on habits, geographical range and synonymy of known forms conclude the article.—Notes to accompany figures of Boisduval's types of six species of Australian *Curculionidae*, by Arthur M. Lea. With the co-operation of Monsieur P. Lesne, of the Paris Museum, the endeavour is made to clear up matters relating to the following species:—*Cryptorrhynchus dromedarius*, *C. lithodermus*, *C. fuliginosus*, *C. ephippiger*, *Gonipterus recticulatus* and *G. notographus*. The types are in the Brussels Museum, and have been examined by M. Lesne, who has forwarded his notes and sketches.—Contributions to the morphology and development of the female urogenital organs in the *Marsupialia*, Nos. ii.–v., by Jas. P. Hill.—Descriptions of two new species of Phytophagous Hymenoptera referable to the families *Oryssidae* and *Tenthredinidae*, with notes on other saw-flies, by Gilbert Turner. A species of *Oryssus*, a genus not hitherto recorded from Australia, and one of *Clarissa* are described, both from Mackay, Q. In the same locality the author has also collected five species of *Perga*, one of *Hylotoma*, four of *Pterygophorus*, and one of *Clarissa*.—On the measurement of bacteria, by R. Greig Smith. The measurement of the breadth of bacteria by the eye-piece micrometer is uncertain because the unit of measurement (one division) is generally larger than the object measured. The author has tabulated a number of diagrammatic bacteria, the breadth of which is expressed in terms of the length.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 15.

ROYAL SOCIETY, at 4.30.—Argon and its Companions: Prof. Ramsay, F.R.S., and Dr. Travers.—Data for the Problem of Evolution in Man. VI. A First Study of the Correlation of the Human Skull: Dr. Alice Lee and Prof. K. Pearson, F.R.S.—Mathematical Contributions to the Theory of Evolution. IX. On the Principle of Homotyposis and its Relation to Heredity, to the Variability of the Individual and to that of the Race. Part I. Homotyposis in the Vegetable Kingdom: Prof. K. Pearson, F.R.S.—A Chemical Study of the Phosphoric Acid and Potash Contents of the Wheat Soils of Broadbalk Field, Rothamsted: Dr. B. Dyer.

LINNEAN SOCIETY, at 8.—Contributions to the Comparative Anatomy of the Cycadaceæ: W. C. Worsdell.—On a New Parasitic Copepod: Miss Alice L. Embleton.

CHEMICAL SOCIETY, at 8.—The Bases contained in Scottish Shale Oil: F. C. Garrett and Dr. J. A. Smythe.

FRIDAY, NOVEMBER 16.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Capacity of Railway Waggons as affecting Cost of Transport: D. Twinberrow.

ANATOMICAL SOCIETY, at 4.30.—Notes on the Hair-slope in Man: Dr. Walter Kidd.—The Origin of the Vertebrate Eyes and the Meaning of the Second Pair of Cranial Nerves: Dr. W. H. Gaskell, F.R.S.

TUESDAY, NOVEMBER 20.

ZOOLOGICAL SOCIETY, at 8.30.—Contributions towards a Knowledge of the Osteology of the Pigmy Whale (*Neobalaena marginata*: F. E. Beddard, F.R.S.—A Description of *Wynyardia bassiana*, a Fossil Marsupial from the Tertiary Beds of Table Cape, Tasmania: Prof. Baldwin Spencer.—On some Crustaceans from the South Pacific. Part V. Arthrostracans and Barnacles: L. A. Borradaile.—List of Mammals obtained by Dr. Donaldson Smith during his Recent Journey from Lake Rudolf to the Upper Nile: Oldfield Thomas.

ROYAL STATISTICAL SOCIETY, at 5.—On the Distribution of Population in England and Wales, and its Progress in the Period of Ninety Years, from 1801 to 1891: T. A. Welton.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Paper to be further discussed*: The Metropolitan Terminus of the Great Central Railway: G. A. Hobson and E. Wragge.—*Paper to be read, time permitting*: Machinery for the Manufacture of Smokeless Powder: Oscar Guttmann.

WEDNESDAY, NOVEMBER 21.

SOCIETY OF ARTS, at 8.—Opening Address of the 147th Session, by Sir John Evans, K.C.B., F.R.S.

GEOLOGICAL SOCIETY, at 8.—On a Monchiquite from Mount Girnar, Junagarh (Kathiawar): Dr. J. W. Evans.—On some Altered Tufaceous Rhyolitic Rocks from Dufton Pike (Westmorland): Frank Rutley.—On the Geology of Mynydd y Garn (Anglesea): C A. Matley.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—An Improved Mounting for the Lens and Bowl of the Campbell-Stokes Sunshine Recorder: Richard H. Curtis.—Weekly Death Rate and Temperature Curves, 1890–1899: W. H. Dines.—Seasonal Rainfall of the British Islands: Henry Mellish.

ROYAL MICROSCOPICAL SOCIETY, at 7.30.—Exhibition of Slides illustrating the Structure of Shells.

ENTOMOLOGICAL SOCIETY, at 8

THURSDAY, NOVEMBER 22.

ROYAL SOCIETY, at 4.30.—*Probable* papers: The Histology of the Cell Wall, with Special Reference to the Mode of Connection of Cells: W. Gardiner, F.RS., and A. W. Hill. Part I. The Distribution and Character of "Connecting Threads" in the Tissues of *Pinus sylvestris* and other Allied Species: A. W. Hill.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Telegraphs and Telephones at the Paris Exhibition, 1900: John Gavey.

FRIDAY, NOVEMBER 23.

PHYSICAL SOCIETY, at 5.—The Anomalous Dispersion of Carbon: Prof. R. W. Wood.—The Liquefaction of Hydrogen: M. W. Travers.—On the Refraction of Sound by Wind: Dr. R. H. Barton.

CONTENTS.

THURSDAY, NOVEMBER 22, 1900.

THE CORRESPONDENCE OF BERZELIUS AND SCHÖNBEIN.

The Letters of Jöns Jacob Berzelius and Christian Friedrich Schönbein, 1836–1847. Edited by Georg W. A. Kahlbaum. Translated by Francis V. Darbishire, Ph.D., and N. V. Sidgwick. Pp. 112. (London, Edinburgh and Oxford, Williams and Norgate, 1900.)

IN collecting materials for the life of Schönbein, the first instalment of which has already been noticed in these columns, Dr. Kahlbaum has had placed at his disposal all the correspondence, covering nearly fifty years, left behind him by the illustrious discoverer of ozone and gun-cotton. The letters of Faraday and Liebig have thus been made public, and we have now an English edition of the letters which passed between Berzelius and Schönbein, the original edition in German having been prepared by the editor as a tribute to the memory of Berzelius on the occasion of the commemoration at Stockholm, on October 9, 1898, of the fiftieth anniversary of the death of the great Swedish chemist. The translators have added two of Schönbein's letters written in 1847, and a paper by that author which was not included in the German edition. Of the twenty-two letters published in this little volume eight are by Berzelius.

Berzelius was senior to Schönbein by twenty years, and it appears that the latter had about 1827 resolved to go to Stockholm to complete his studies under the "consummate master of chemical science." In order to raise the necessary funds he offered a London bookseller (Koller) a translation of Berzelius' "Lärbok i Kemien," and about the same time he proposed to a German acquaintance (Perthes, of Gotha) to supply a German translation of Gay-Lussac's lectures on physics, which he was then attending at the Sorbonne. Neither of these schemes came to anything, and Schönbein was, as already recorded in his life, invited to Bâle as temporary professor in 1828. The Swabian chemist thus never came under the personal influence of his Swedish contemporary as a pupil, and the acquaintance was commenced in 1836 by a letter, in which Schönbein submitted the results of his experiments on the passivity of iron. In this letter, which is the first of the present series, he describes himself to Berzelius as "a perfect stranger." The reply, dated May 4, 1837, is interesting, not only because it is the first communication from Berzelius, but also because it at once emphasises the difference of opinion which at that time separated the two schools of "contact" and "chemical" electricians. Having suggested that the iron by contact becomes charged with opposite electricity, he goes on to say:

"But of course you cannot admit the latter assumption, since you accept De la Rive's view that electricity of an opposite character cannot be produced by contact. In this, however, I do not agree with you; I am firmly convinced that when we understand the cause of this remarkable property of iron, we shall find in it one more proof that Volta's conception was more profound and nearer the truth than that of his opponents, who, by admitting that electricity and chemical affinity are different manifestations of the same force, acknowledge, though without being conscious of so doing, that Volta was right."

In subsequent letters the prevailing note of the correspondence is still the origin of the electric current and the cause of polarisation. In his letter of October 14, 1838, Schönbein describes the polarisation of liquid electrodes (hydrochloric acid) in a U-tube, and suggests in explanation that the first step in the decomposition of a molecule by electricity is, as it were, a preliminary loosening of the affinities of the atoms:—"Between the complete separation of two elements and their most intimate chemical union there exist intermediate conditions of combination, of which as yet we know nothing; unless indeed isomerism points to some such relation." Berzelius (November 13, 1838) opposes this view, and refers his correspondent to a theory of the galvanic cell which he had advanced thirty-six years previously. The reference to this theory has apparently given the editor, Dr. Kahlbaum, some trouble, but he appears to have identified it and appends a valuable bibliographical footnote. Schönbein's reply (March 28, 1839) contains further arguments against what he calls the "electrochemical theory," meaning, of course, the form of that theory promulgated by Berzelius. He sums up in the statement that "the act of chemical combination of the elements is not due to the play of electrical forces, or, in other words, that affinity and electricity are not the same thing, though they are mutually dependent."

The first reference to ozone in the present correspondence is contained in a letter from Schönbein to Berzelius dated September 11, 1840, in which he refers to the "odoriferous principle" as having already been discovered but not isolated in sufficient quantity to determine its chemical characters. The reply to this communication, of which a copy by Schönbein has been found, was kept by the Crown Prince, subsequently King Maximilian II. of Bavaria, under somewhat interesting circumstances. It appears that the first paper on ozone had been sent by Schönbein to Prof. Schelling, who was then at Munich, and the latter in his reply says:

"In the person of our Crown Prince we possess a distinguished patron of research, especially on scientific lines. Should you ever be unable from want of pecuniary resources to begin a lengthy research, from which you have grounds for expecting good results, let me know, and it will give me great pleasure to awaken the interest of our generous Prince on your behalf."

On the strength of this recommendation Schönbein applied for a grant in order to purchase a battery; but unfortunately the application was received by the Prince just as he was leaving for Greece, and he took the correspondence, including the letter from Berzelius referred to above, away with him, so that nothing resulted from the application.

Passing on to the year 1844, there is a very long letter addressed to Berzelius and containing a fairly complete *résumé* of Schönbein's work on ozone down to that period. It is of interest to read that he sends his correspondent the bleached strip of paper which first "proved the bleaching power of the electrical odour" on April 7, 1844. In this letter also we find the view that nitrogen is a hydride of ozone, and, in curious antithesis to existing

notions, that "certain diseases might be due to ozone." The reply from Berzelius is chiefly remarkable for the cogency of the reasons which he urges against the view that nitrogen is a constituent of ozone, and the friendly spirit in which he urges Schönbein to follow up his investigation "with true Bunsen perseverance."

The letter from Schönbein dated January 15, 1845, contains an account of the production of an "electro-negative oxidising substance" by the slow combustion of ether vapour and phosphorus, by a hydrogen flame and by a candle flame. This was read to the Academy at Stockholm, and Berzelius in his reply considers his correspondent to have proved that ozone is always formed during combustions in atmospheric air. He then goes on to criticise most frankly some of Schönbein's conclusions in a detailed paper published in 1844, he makes excellent suggestions for testing certain points experimentally, and winds up with the remark :—

"It would, therefore, be better to put on one side all theoretical conjectures as to the constitution of ozone and nitrogen, and to study the properties of ozone itself. When once you have caught it, it will be easier to theorise about it."

In his reply Schönbein explains that much of his correspondent's criticism had arisen from the misrepresentation of his views owing to the bad rendering of his paper into French, but he candidly and gratefully accepts the remainder. He still clings, however, to the possibility of nitrogen being a compound, and adds a remark to the effect that even if this hypothesis were baseless, it had guided him in all his experiments and had led him to many discoveries.

A letter of Schönbein's dated March 22, 1845, is of particular interest from several points of view. It was communicated by Berzelius to the Stockholm Academy, together with another letter from Plantamour, of Geneva, which contained a description of Marignac's first experiments and conclusions respecting ozone. Schönbein in his letter refers also to the work of his friend Marignac, and describes the results to Berzelius. He considered that his and Marignac's experiments confirm one another, and he adds :—

"I think we may fairly conclude from them that oxygen and hydrogen are the constituents of ozone."

Thus he had by that time abandoned the view that nitrogen had anything to do with ozone, and it is quite exciting, even at the present time, to read in this letter how near he was to the explanation of the true nature of ozone, and yet how he missed the path. He gives convincing reasons for believing that ozone and Thénard's hydrogen peroxide were distinct, and he proves by experiment that ozone is destroyed by passing through a hot tube. Yet it seems to have been first suggested by Plantamour, in a letter to Berzelius dated April 20, 1845, that ozone was not a compound, but only a form of oxygen, although in the paper printed as an appendix to the present volume Schönbein speaks of this view as having been originated by De la Rive.

The subsequent letters teem with interest especially when, as in that dated June 20, 1846, the practical applications of gun-cotton begin to figure in the correspondence. The King of Sweden, at the instigation of Berzelius, sent Schönbein the Vasa Medal in February, 1847. On March 12 of that year Berzelius addressed a long letter to Schönbein full of the most friendly and candid criticism of his views on the chemical nature of nitric acid and ozone. From this it appears that Schönbein still believed that ozone contained hydrogen, for his correspondent says :—

"But does ozone really contain hydrogen? This question we can answer most emphatically in the negative. If oxygen gas collected during the last third of its evolution from potassium chlorate be exposed to a series of short electric sparks, ozone is formed just as readily and to precisely the same extent as during the first third of the operation. In this case, however, it is physically impossible for water to be present. This constitutes the most indisputable proof that ozone does not contain hydrogen. Hence it follows that ozone is an allotropic modification of oxygen itself, &c."

The criticisms in this letter are altogether very vigorous, and Berzelius lays down a principle at the outset of his attack which it would have been well to have kept in view in many "modern instances" of theorising :—

"The test of the truth of a theory is that it should harmonise the particular instance with the whole system of science; for the laws of nature are always consistent with one another. Now if you advance a principle which makes an exception of what was before consistent with scientific ideas, logic pronounces against you."

He concludes by begging his correspondent to excuse his preaching, and hopes he will not refuse to learn. It is, no doubt, only a coincidence, but this, the last letter from Berzelius, is the only one in which the Swedish chemist winds up with the subscription, "Farewell, yours sincerely." The reply by Schönbein, dated March 29, 1847, contains a further defence of his views concerning the nature of ozone and nitric acid, and begs in conclusion for a letter from Berzelius stating that he (Schönbein) was the first discoverer of gun-cotton. He had patented this explosive in England, and says that his patent "will undoubtedly be contested."

Berzelius died August 7, 1848, and the editor has discovered a short sketch of an obituary notice by Schönbein which was apparently never published, but which had been hastily written on a sheet of paper partly covered by the draft of a letter to Faraday. The position occupied in the world of science by the illustrious Swede needs no further definition at the present day, but this short estimate of his achievements by his contemporary Schönbein will still be read with interest.

We have once again to express our obligations to Dr. Kahlbaum and his colleagues for a remarkably interesting little contribution to the history of chemistry.

R. MELDOLA.

SOME OBSERVATIONS ON ANIMAL HYPNOTISM.

Beiträge zur Physiologie des Centralnervensystems. Von Max Verworn, a.o. Professor an der Universität Jena. Erster Theil. Die sogenannte Hypnose der Thiere. Pp. iv + 92; and 18 figures. (Jena: J. Fischer, 1898.)

THIS volume by Prof. Verworn, on the phenomenon of so-called hypnotism in the lower animals, is a clear and exhaustive account of the subject. Paucity

of knowledge renders the theme one very limited for scientific treatment. During the past two and a half centuries, various inquirers into nature, from Daniel Schwenter and the Jesuit Father Kircher onwards, noted that by handling animals it is possible to impose upon them postures. Though strained, these are for a time maintained after release from the hands of the "operator." This "animal plasticity" recalls the plasticity of the human subject in the cataleptic phase of hypnosis. In human hypnosis, however, the cataleptic rigidity is only one, and not the most striking, of a set of concurrent symptoms contributing to make up the hypnotic state. Abeyance of will, ultra-sensitivity of the senses, contraction of the field of attention with substitution of passivity for activity, appropriate response to complex sensorial stimuli of the organs of vision and hearing, execution of acts resembling those of volition, paralysis of memory, all these characters of hypnotism predicate a mental organisation much higher than can be attributed to the majority of creatures in which the so-called "animal hypnotism" can be induced. These remain, therefore, almost without counterpart in "animal hypnotism." If it is permissible to speak of "will" in dealing with neural types so far removed from human as those of the crayfish and the amphibian, there does occur in animal hypnotism what resembles suspension of "willed" action. The animal remains motionless for long periods in postures which it has been constrained to assume. The guinea-pig is, as regards neural organisation, the highest type in which the phenomenon has been at all systematically studied. Both cat and dog are reported "refractory." It is true a condition characterised by cataleptoid plasticity has been observed in the monkey subsequent to extirpation of its cerebral hemispheres. The animal then enters a peculiar state known as "decerebrate rigidity," of which a spastic contraction of the extensor muscles of the limbs and trunk is characteristic. That this condition in the monkey is allied to that termed "animal hypnotism" is strongly suggested by the fact that, as Heubel first showed, the induction of so-called hypnotism in the lower types is favoured by decerebration, and the plasticity is more pronounced in decerebrate than in intact animals.

Prof. Verworn has succeeded in obtaining graphic records of the contraction of the implicated muscles during their condition of tonic rigidity. He notes that the constrained postures in which the rigid animal remains are all of them attitudes assumed in attempt at recovery of the normal from an abnormal posture, *e.g.* in attempt to right itself after being placed over on its back. When the creature breaks from the spell its escape is usually sudden. Those muscles, then, that have been in tonic contraction do not relax, but by contracting further complete the execution of the movement toward which the posture was an approach.

The long continuance of the hypnotic tonic contraction leads Prof. Verworn to conclude that there must, during its course, become established in the nerve-cells and muscle-cells an equilibrium between assimilation and dissimilation. This instance induces him to sketch the theory of the chemical exchanges involved in cell-life. The cell must, as a chemical machine, be able to live and work at various rates all equally without exhaustion. A faster rate of liberation of energy by decomposition of the molecules is met by faster replenishment of energy by the synthesis of new molecules. The author speaks of the functional activity of the cell in relation to its metabolism as "biotonus," *e.g.* the biotonus of the nerve-cell. The Jena school of physiology is so closely associated with the teaching of the elder Hering, to whom we owe the theory of assimilation and dissimilation as colligate functions of protoplasm, that no doubt the sketch given by Verworn is not intended to challenge comparison with Hering's essays. It is probably intended to fall into place as an item toward the general promulgation of Hering's fundamental doctrine; this it does, though the exact application of the theory to the as yet insufficiently analysed phenomenon of animal hypnotism is not so definite as that of some other examples that could more easily have been found.

The volume is altogether an interesting one. It is considerably enhanced in value by thirteen excellent figure photographs from nature of animals in the condition of the so-called "hypnosis." C. S. S.

OUR BOOK SHELF.

Memoranda of the Origin, Plan and Results of the Experiments conducted at Rothamsted; Fifty-seventh Year of the Experiments, 1900. (Issued by the Committee.)

THE history of this publication is worth noting. It first appeared in 1855, the year of the opening of the new laboratory at Rothamsted, and was issued for the use of the numerous visitors to the experiments; it then consisted of four pages, giving the last year's produce on some of the experimental fields, and the scheme of cropping and manuring of the other fields on the farm. The next issue was in 1862, when the average produce on each plot was given. For some years it was not published annually, but supplements were from time to time issued. Annual publication commenced in 1872. In 1878, a preface giving an account of the origin and scope of the Rothamsted experiments was added, with a list of the papers already published. But little alteration in its character has since taken place, though the additions have been considerable. The present volume contains 120 pages, and supplies plans of the experimental fields.

The "Memoranda" do not furnish a report of the work done at Rothamsted by Messrs. Lawes and Gilbert, except so far as this is shown by the preface reprinted each year, and the lists of papers. The pages are mostly occupied by a mass of figures, showing the manuring, and the average produce on each experimental plot with the produce of the last year. There are also tables giving some particulars of the chemical composition of the sugar beet, mangel wurzel, and potatoes grown by various manures. There is little or no discussion of the numerical results recorded, but most of the sections begin with some remarks elucidating the general character of the experiment next described.

As the produce yielded by nearly every experimental plot is annually published in these "Memoranda," the record is one of great value to the student, especially if he has at his disposal a complete series of the earlier issues. When thus furnished he is able to study the results of the experiments in a very thorough way, having a complete up-to-date record to work on. Unfortunately, however, this is just the kind of publication which is seldom saved and bound for reference, and it is doubtful if many complete sets now exist.

The tables of the "Memoranda" are little suited for the use of the popular writer, and sad mistakes are

sometimes made by the agricultural press in their quotations from them. This is generally due to the alterations in the manures on some of the plots during the long course of the experiments, the average produce of the plot given in the table thus sometimes bears no relation to the manure which the plot is now receiving. In the summary tables now separately printed for the use of visitors to the fields these errors are avoided by calculating the average produce for those periods only to which the present manuring applies.

A melancholy interest attaches to the present issue of the "Memoranda" as being the last with which Sir J. B. Lawes, the founder of experiments, will be personally connected. R. W.

The Scenery and Geology of the Peak of Derbyshire. By Elizabeth Dale. Pp. viii + 176. (Buxton: C. F. Wardley. London: Sampson Low and Co., Ltd., 1900.)

THE main object of the author, who is Pfeiffer student of Girton College, Cambridge, "has been to give a simple account of the geology of this most interesting district, treating this limited subject in such a way as will make it possible for the book to serve as an introduction to the study of the science." That this purpose has been carried out in a thorough and praiseworthy manner will not be questioned. Miss Dale is well acquainted with the district; she has herself contributed to our stock of knowledge, and has gathered other information from the best authorities. The country of the Peak is attractive to lovers of scenery as well as geological students; and a handy volume which tells as this does of the numerous fine sections, of good localities for fossils, of the origin of the physical features and of the caverns and their varied contents, is sure to be appreciated. We doubt, however, the wisdom of introducing so much general geology in what is essentially a local guide. It would have been enough to point out the lessons to be derived from the rocks in the district without dealing with other matters, such as the nebular theory, or the growth of geology and its relation to modern thought. Those who reside in Derbyshire, and have no other geological books, may be glad to have such full information; but those who want only the local facts, and explanations of them, will not be so pleased. The work throughout bears evidence of painstaking research, and we notice very few errata. The book has a somewhat provincial aspect in its "get up;" some groups of illustrations, when they occupy a whole page in the text, are notified as plates, while, curiously enough, Plate vii. is placed before Plate vi. There is a well-printed and clear geological map of Buxton and neighbourhood; but it ends off in the middle of Kinderscout, which is marked on the map as "The Peak." The pictorial illustrations are fairly good; they would have been excellent if well printed.

Malaria. By Angelo Celli, Director of the Institute of Hygiene, University of Rome. Translated by John Joseph Eyre, with an introduction by Dr. Patrick Manson. Pp. xxiv + 275. (London: Longmans and Co., 1900.)

SINCE Laveran's great discovery of its parasitic nature, war has been waged with ever-increasing vigour against malaria, and Italy has always been in the forefront of the battle.

The fortunate combination of an ample supply of material and men capable of taking advantage of it has resulted in great and important additions being made to our knowledge of the fever and its etiology.

Among the Italian workers Prof. Celli is one of the most prominent, and the present volume, founded on a recent course of lectures delivered in Rome, gives us a cursory glance at much of the work on which his eminence is based.

By dealing, as he does here, only with the malaria fevers of the Roman Campagna, Prof. Celli loses nothing in interest, for though we agree with him when he says malaria is a local phenomenon which must be studied on the spot, and data gathered in a particular territory cannot be generalised, yet a book that will enable English readers to readily acquire a succinct and fairly complete knowledge of the recent progress towards the elucidation of the malaria mystery cannot fail to be gladly welcomed.

The lectures contain necessarily much that is true without being new, and the information, though sound on the whole, is on some points rather scanty. This is specially true of the description given of the various mosquitoes responsible for Roman malaria; the information on this point is slender and quite inadequate for the identification of species. The bionomics of the mosquitoes are also insufficiently detailed, and several important points are omitted. No mention is made of the peculiar attitude assumed by Anopheles when at rest, nor is the tendency of Culex to lay their eggs in artificial receptacles of water noticed.

It is, moreover, inaccurate to say that mosquitoes live only in low-lying places. In British Central Africa they have been found at an altitude of several thousand feet.

One of the best parts of the book is that which deals with the local or physical causes of predisposition or of immunity, and it will be seen how remarkably it agrees with the accounts of similar observations in other parts of the world. Readers who are aware of the efforts now being made to improve the conditions of European life in the tropics will appreciate the emphasis with which this part of the subject is treated.

Part ii. deals with Prophylaxis in its various aspects, and here the author is at his best. The advice he gives is excellent and practical, and if intelligently followed would greatly reduce the ravages of malaria. No mention is, however, made of either mosquito curtains or punkahs. It is satisfactory that justice is done to Ross's epoch-making work, an example which might well be followed by some other Italian writers.

The nomenclature differs somewhat from that now generally adopted in England; hæmosporidia being substituted for hæmamœbidæ, and sporozoites for blasts.

The translator has done his work well, though his choice of words is not always good. The illustrations are good throughout, but we think it a mistake to represent the mature zygote in Fig. 19 as possessing a double-walled capsule, and the unstained blasts on the same plate are not correctly depicted.

A Year with Nature. By W. P. Westell. Pp. xvi + 276. Illustrated. 8vo. (London: H. J. Deane, 1900.)

WITH every desire to be charitable to an author who, so far as we are aware, has seen his work "within covers" for the first time during the present year, we are fain to confess ourselves at a loss to conjecture the class of readers for whom the volume before us is intended. Clearly it is not for the professional naturalist; and we doubt whether the average reader interested in natural history will find much entertainment in its pages.

Apparently the general plan of the work is intended to be a kind of naturalists' calendar, but intercalated in several of the chapters are essays on subjects which seem to have no connection with the one in hand. We fail, for instance, to see any connection between birds' tails and October, or between their beaks and September; neither do we realise the affinity between January and Mr. Rothschild's museum at Tring Park—certainly none such could have been suggested by the author's reception when he visited that admirable institution.

In his preface the author very candidly, although perhaps somewhat superfluously, informs his readers that he has "not tried to cultivate any literary style or artistic merit." He might have added that his mode of

framing a sentence is such as, at times, to convey to his readers a meaning totally different from the one he intended, and also that he is not always acquainted with the signification of the terms he employs. As an example of the former kind of error we may refer our readers to p. 17, where it is stated that antelopes and snow-leopards are "denizens of the deep"; while as a sample of the second we may adduce the misapplication of the term "antlers" to the cranial appendages of sheep (p. 26).

Admitting that Mr. Westell displays a strong love of nature, the best we can say of the text in general is that, for the most part, it consists of descriptions of what may be seen during a country walk at different seasons of the year, interspersed with platitudes and reflections, and extracts from poems. We have, however, failed to detect anything strikingly original either in the proper subject of the book or in the articles devoted to the discussion of the beaks, tails and feet of birds. The article on the Rothschild museum and menagerie seems chiefly intended to display the author's profound ignorance of natural history in general.

The one redeeming feature of the book is to be found in the illustrations, which are exquisite examples of photogravure; and if it consisted of these alone (which, by the way, have been photographed by friends of the author), it would certainly form a pretty picture-book for the drawing-room table. But, as the author is once again candid enough to admit, the illustrations, for the most part, have no sort of connection with the text, and are, so to speak, thrown in at haphazard.

A few of the articles, it seems, have previously appeared in magazines; while the majority or all of the rest were first published in the columns of certain local newspapers circulating in the home counties. In our own opinion, the author would have been better advised had he been content with the credit to be derived from such ephemeral publication. R. L.

The Geology of Sydney and the Blue Mountains: a Popular Introduction to the Study of Geology. By the Rev. J. Milne Curran. Second edition. Pp. 391. (Sydney: Angus and Robertson, 1899. London: Australian Book Co., 38, West Smithfield.)

THIS is, strictly speaking, an elementary manual of geology, written and illustrated with especial reference to the geology of Sydney. The general plan of the work is good; the book is well printed and illustrated with maps, photographic pictures of rock structure and scenery, figures of fossils and rock sections; and it is satisfactory to learn that the labours of the author have been appreciated, as the first edition, published in 1898, was sold out in a few months. This speaks well for the interest taken in the study of geology in New South Wales. The colony is fortunate in having representatives of all the great geological systems from the Silurian upwards, but it is sufficient for the Australian student to learn the forms of life which characterise these main divisions all the world over, while he supplements the knowledge with particulars of the strata and organic remains in his own country. To him information about the Hawkesbury-Wianamatta series or the Mount Lambie sandstones is more important than a description of the Wenlock Limestone, the Lower Greensand or the London Clay.

The author gives general accounts of fossils, minerals, and rocks, but he sometimes becomes too popular in style, as, for instance, when he remarks of the Labyrinthodon, that "This ungainly creature was a shovel-headed Salamander, which pottered about like Falstaff in his old age, 'with much belly and little legs.'" To be very popular and also exact is difficult, and in this respect the author is not wholly successful.

Information is tabulated and repeated almost to excess; there is a table of the stratified rocks of New South Wales, another of the principal Australian sedimentary formations, and a third of the general succession of Australasian strata, to say nothing of minor tables. The characteristic fossils of the Australian formations are enumerated (pp. 84, 85), but in so erratic a fashion that saurians, fishes, echinoderms and mollusca are hopelessly mixed.

The author observes in his preface (p. 8) that "some friendly critics have found fault with the disposition of the illustrations." These critics were quite right. There is no excuse for placing a figure of the Triassic *Trematotus* in a page dealing with Pleistocene, nor a figure of remarkable weathering of sandstone in a page treating of basalt!

The sketch map which serves as frontispiece has no scale attached to it, while the coloured geological map of Mount Victoria, Blackheath and Hartley takes in a part of the Blue Mountains, though the fact is not made manifest. It is desirable that references be given in all cases where quotations on scientific subjects are made, and it would be well to add the initials of authors in the list of works given in the appendix.

The author concludes his work with a glossary. We doubt the utility of giving the derivations of many biological names; some of these appear ludicrous, as, for instance, *Agnostus* (I know not), *Athyris* (without a door), *Avicula* (a little bird), *Phanerogams* (visible marriage), &c. These, however, are trifling matters. The book is one on which further pains may advantageously be bestowed, as it is sure soon to reach a third edition.

Light Railways at Home and Abroad. By. W. H. Cole, M.I.C.E. Pp. x + 339. (London: C. Griffin and Co., Ltd., 1899.)

WHILE it is too soon to say that the Light Railways Act of 1896 has in any degree failed in its object, it must be admitted that as yet there are no signs of that revolution in the transport service of country districts for which the more enthusiastic promoters of the Act had hoped. Of the many schemes that have been brought forward but few have emerged from the successive ordeals of the Light Railway Commissioners and the Board of Trade, and of these several have failed to secure the necessary support of capital. This is hardly to be wondered at, for the districts in which the need of improved facilities for transport is most urgent are precisely those in which the spirit of enterprise and the power of raising capital are weakest. The British agriculturist, too, whether landlord or tenant, has been so long unaccustomed to take joint action for a common end, that many hopeful schemes have failed to obtain the support of those who might be expected to reap the chief benefit from them. It may be that the provisions of the Act require modification, that the Board of Trade must become less exacting in its conditions, that greater encouragement must be given to local authorities, or easier access afforded to Treasury grants. These are questions which a few years working of the Act will answer.

Meantime, to all who are interested in the subject of light railways, whether as promoter, engineer, or possible user, Mr. Cole's book is indispensable. His object has been to collect all available information from many scattered sources, and to condense and present it in compact and accessible form, and he has succeeded in producing a very useful book of reference. Something more than a hundred pages are devoted to light railways abroad, special attention being given to their development in Belgium, France, Italy and India. In each case full details are given as to the provision of capital, whether by the State, by local authorities or by private enterprise; as to gauge, weight of rolling stock, use of highways and other details of construction; as to various economies of working, limits of speed and precautions

for safety; and, lastly, as to the financial return and the disposal of profits when such exist.

The second portion of the book is more directly concerned with light railway development in England. A useful chapter is concerned with an analysis of the Act of 1896, while the special chapters on "The Question of Gauge" and on "The Construction and Working of Light Railways" are perhaps the most valuable in the book. On the question of gauge it may be worth while to quote Mr. Cole's conclusion, which is that for railways making connection with main lines the standard gauge is imperative, and that for smaller independent lines the reduced gauge of thirty inches may be used. In this connection we notice no reference to the Duke of Westminster's narrow-gauge railway at Eaton Hall, though this is, perhaps, the most instructive example of a small and self-contained railway in the United Kingdom.

The book contains a number of folding plates, showing details of construction both of permanent way and of rolling stock; and a long appendix includes tables of returns for many railways, both of standard and of light construction, as well as the full text of the Act of 1896 and its schedules.

Les Plaques sensibles au Champ électrostatique. Par V. Schaffers, S.J. Pp. xxxix + 19. (Paris: A. Hermann, Librairie Scientifique, 1900.)

THE phenomena treated of in this pamphlet are those observed when an electric discharge from a powerful Whimshurst was passed over the film of a photographic plate between two metallic points which usually were both in contact with the film. A great variety of films, containing various metallic salts mixed with different emulsions, &c., besides those ordinarily used for photographic purposes, were tried.

The potential difference used was not enough to spark across between the poles, and the changes produced in the films are probably mainly due to the current through the film, and not to the discharges through the air above it. In some cases the marks produced on the plate were approximately parallel to the lines of electrostatic force or current stream lines through the film, and several plates are given showing the effects obtained in such cases. A considerable variety of peculiar and more or less interesting appearances are clearly described, and possible explanations of them discussed. Scarcely any variations in the method of submitting the material to the action of the discharge were tried, and the object of the experimenter seems to have been more to obtain a large variety of peculiar appearances than to really elucidate the nature of the actions taking place. The method of obtaining pictures of the lines of force or current stream lines between conductors on the plates is described in detail, and such pictures as the author points out may be useful for educational purposes in some cases.

H. A. W.

The Elements of Plane Trigonometry. By Prof. W. P. Durfee. Pp. vi+105. (Boston, U.S.A.: Ginn & Co., 1900.)

THERE are a few novel points in this book. Logarithms and their use in computations are dealt with in the first chapter, and most of the exercises are of a character which will lead the student to see that trigonometry has a practical value. The second chapter deals with trigonometrical ratios, and is followed by chapters on unlimited angles, reduction formulæ, the addition theorem, relations between the sides of a triangle and the trigonometrical functions of its angles, and solution of triangles. Logarithms are used in all the calculations. The course of work in the book is suitable for elementary students of trigonometry, and constitutes an introduction to the theory of functions as illustrated by trigonometrical ratios.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Autotomic Curves.

MR. RICHMOND's letter appears to be written under a misapprehension. My objection to such phrases as "non-singular cubic curve," "non-singular curve of the *n*th order," arises from the fact that a point of inflexion is just as much a singularity as a node, and that it is therefore inaccurate and misleading to describe such curves as non-singular. In fact, the only non-singular curves which exist are conic sections; all others are singular. On the other hand, the word autotomic exactly expresses the idea it is desired to convey; and I have been informed by several excellent Greek scholars that they do not consider the phrase "an anautotomic curve" open to objection, and that the alliteration may be frequently avoided by the use of the words every or any instead of an.

The terms *sesecting* and *non-sesecting* appear to be unobjectionable from a literary point of view; but with regard to *unautotomic* and *nodeless* there is a general consensus of opinion amongst writers who are careful about their style against the use of hybrid terms composed of words belonging to two different languages.

A Remarkable Dolphin.

DR. WAY, the headmaster of Rossall School, has recently forwarded to the Natural History Museum (for determination) portions of a cetacean stranded at Rossall in September. These portions include the skull, the imperfect flippers, the tail (including the caudal vertebræ), and the back-fin.

The skull and other bones leave no doubt that the animal is the bottle-nosed dolphin (*Tursiops tursio*). In place, however, of the ordinary "flukes" of a dolphin, the tail terminates in two long, narrow lobes, of which one is very much longer than the other; and, were it not placed in a horizontal instead of a vertical plane, it might well be mistaken for the tail of a thresher shark. The larger lobe of the tail measures 5 feet 3 inches, while the total length of the remainder of the creature was 10 feet. A similar abnormal elongation is noticeable in the case of the back-fin, which is about twice as long as ordinary, and proportionately slender. Externally, both the tail and the back-fin are thickly coated with small sea-weeds and sertularians.

Judging from the teeth, the animal appears to be very aged, and the only conjecture I can make in regard to the tail and back-fin is that their abnormal form is due to pathological hypertrophy, perhaps induced by an injury. I should be glad to hear of any other instances of analogous malformation among cetaceans.

The Optics of Acuteness of Sight.

OBSERVATIONS have been frequently made upon the remarkable eyesight of certain uncivilised tribes. Travellers have told us of guides who could see four of Jupiter's satellites with the unaided eye; and lately Sir Redvers Buller has declared that the average Boer can see at least two miles further than the British soldier. It is of some interest to consider whether this superiority is due to a real change in the optical properties of the eye, or merely to some special ability to interpret slight differences of impression, which might be acquired by practice. As we have as yet no data as to the constants of a Boer's eye, we may raise the question whether such feats are optically impossible for an Englishman's eye.

The minimum visual angle is determined by the transverse diameter (c) of a foveal retinal cone, and its distance (F″K″) from the second nodal point of the eye. We have—

$$\tan\frac{\alpha}{2} = \frac{\frac{1}{2}c}{F''K''}$$

and, where $c = \cdot 002$ mm., $F'K'' = 15\cdot 498$ mm.

$$\alpha = 26\cdot 618''$$

In order that two points may be distinguished as such by the

eye, their retinal images must be separated by at least one unexcited retinal cone. The distance between the two images must therefore be ·004 mm., or the intervening cone may be encroached upon. Therefore the minimum visual angle

$$\theta = 2a = 53 \cdot 236''.$$

Now Jupiter's edge and his first satellite may subtend at the sun an angle of 1·33″, so that we may regard this as the average angle subtended at the earth. Hence we see that there is no optical reason why the four satellites should not be seen by the naked eye. If they were sufficiently bright they no doubt could be distinguished by the normal Englishman's eye. "It must be remembered, however," as Sir Michael Foster says, "that the fusion or distinction of sensations is ultimately determined by the brain. The retinal area must be carefully distinguished from the sensational unit, for the sensation is a process whose arena stretches from the retina to certain parts of the brain, and the circumscription of the sensational unit, though it must begin as a retinal area, must also be continued as a cerebral area, the latter corresponding to, and being, as it were, the projection of the former." No amount of education can make the sensational unit smaller than the minimum retinal area, though by practice the cerebral area may be made more sensitive to minute sensational impulses.

ELECTRIC TRACTION TROUBLES.

THE English—the pioneers in the development of railways, steamships, the telegraph, and other inventions of the nineteenth century—are now running the risk of becoming a nation of imitators. Apart from the fact that the entire route, Shepherd's Bush to the Bank, was not sent bodily across the Atlantic to be tunnelled, the Central London Railway might almost as well have been constructed in Central America as in Central London.

For not merely did the steam-engines come from Milwaukee, the electric lifts from New York, the dynamos, locomotives, and other electric apparatus from Schenectady, but the curious practice of requiring a passenger to first purchase a ticket and then drop it immediately into a box, as well as the projection of information into each end of a car on quitting each station are Yankee notions, and one expects to hear that the "next station is Chippawa" or Winettea, and not commonplace Bond Street or Oxford Circus.

The characteristics of American traction are convenience, comfort, speed, low fares and a liberal scattering of the electric current over the district generally. Chinese like, we have faithfully adopted them all. To go from the City to the Albert Hall, up to this summer, one went, of course, from the Mansion House to the South Kensington railway stations. Now one saves time and money by being whisked electrically to Lancaster Gate and walking across Kensington Gardens. No wonder, then, on C.I.V. Monday 230,000 people used the Central London Railway, enough passengers, in fact, to fill every seat one and a quarter times in every train from early morn on Monday to the small hours of the following day.

No need to issue return tickets at reduced rates when every passenger who goes by this line can be relied upon to return by it. What matters it, then—may think the artisan, the clerk, the stockbroker, the investor, and even, perhaps, the engineers and directors of the Central London Railway itself—by what route the electric current returns? The electric current that starts from the Marble Arch, say, must, from the nature of things, go back there. Why, then, should advantages be offered it that are not thought necessary in the case of the general public to induce a return home inside the tube?

If one were a shareholder *only* of the Central London Railway, one might find it difficult to realise that any other interest was of any consequence. But, if a considerable portion of one's income happens to be derived from dividends on the shares in gas and water companies, one may prefer that these sources of income shall not be seriously interfered with. Hence, the clean white glazed brick walls, the brilliant arc lamps, the pleasant gliding lifts, the entire absence of those rolling clouds of smoky steam that greet a passenger as he descends into the Euston Road on a damp, cold November day, fail to cheer him on his swift modern progress under Oxford Street, should he make the following little elementary calculations:—Over 2000 electric horse-power which, at times, every day is already actually put into the Central London Railway at a single sub-station between Shepherd's Bush and the Bank means a current of over 3000 amperes; and this current, after passing through the electro-motors on the trains in the neighbourhood of that sub-station, has to come back there through the *uninsulated* rails on which the trains run. Suppose, in consequence of these rails being *un*insulated, 10 per cent. of this return current strays outside the iron tube and comes back by the iron gas and water pipes running parallel with the railway on the ground above it. This means about $\frac{3}{4}$lb. of iron removed from the gas and water pipes in an hour in the neighbourhood of a sub-station.

Such large currents, however, as 3000 amperes are at present probably only seldom reached, therefore, to avoid even an approach to exaggeration, let us assume that the average current which strays into the gas and water pipes on its way back to a sub-station is only, say, $\frac{1}{100}$th of the maximum value of the current leaving a sub-station each day. This seems a modest enough estimate. Then, since the line works some eighteen or more hours per day, this means about *a quarter of a ton of iron* removed per year from the gas and water pipes in the neighbourhood of *each* of the places at which the current is fed into the railway. Consequently, as there are several such places between Shepherd's Bush and the Bank, this would lead to more than *one ton of iron* being eaten out of the pipes each year.

Is this important? Well, as holders of gas and water companies shares we should say, very! But are the travelling facilities of the London public to be interfered with, is the development of electric traction to be hampered—just when our people are having their first taste of the immense advantages that accrue from propelling trains and tramcars by electricity—simply because several millions sterling happen to have been invested on pipes, retorts, gasometers, waterworks, &c., and because there are people so blind as to actually prefer the receipts of regular dividends to the slavish copy of American practice?

Luckily, no such terrible alternative need be flourished in the faces of our democratic governing bodies, who, while naturally anxious to defend the people from the supposed extortions of the gas and water companies, are no less anxious to shield from the incursions of the electric traction capitalist a large class of persons with small incomes who have placed their savings in what they rightly regarded as safe investments—viz., the shares of gas companies.

Another electric service has been inaugurated this year in which trains as large as, or larger than, those on the Central London Railway are driven electrically over a far more difficult route—viz., from Earl's Court to High Street, Kensington, among ordinary trains over points and crossings.

And yet, in spite of this greater difficulty, there is not merely an insulated conductor to take the electric current to the trains, as on the Central London Railway, but also an insulated conductor to bring it back by; and the rails on which the electric trains run between Earl's Court and High Street, Kensington, are used simply for

what they were originally put there—viz., to carry the weight of the train, and not to ineffectually carry an electric current also. Such a system enormously diminishes the electrolytic corrosion of gas and water pipes; and, since it is a system that has been designed by a celebrated firm of consulting electrical engineers and carried out by a no less celebrated firm of electrical contractors, surely nobody suggests that it is in any sense impracticable.

It will be urged, however, that on that vast network of tramways lying between Uxbridge Road and Acton, Hammersmith and Hounslow, Kew and Richmond, &c., which will shortly be worked electrically, two overhead insulated conductors are impossible, and we must adopt the American system. Yes, but what American system? The conduit system, for example, employed already for years in Washington, and of which some seventy miles now exist in New York, in which there are no overhead wires at all, but an insulated going and an insulated return conductor, both under the street? Or is all this too modern for England, and can we not project ourselves in advance of where America was several years ago, and must we resort to the old insulated trolley wire to take the current and the *un*insulated rails to bring it back?

Why, only recently there was suggested, in one of the technical papers, a proposal to overcome all this difficulty in the case of street electric tramways by taking the current to the cars by means of an overhead trolley wire as hitherto, but using instead of the rails as the return conductor an *insulated* cable which was connected automatically with a car as it passed along and which, differing in potential from the earth by only a few volts, could not give rise to appreciable leakage to the ground. Will an insuperable barrier to a trial of such an English system be found in the fact that its parent, called "surface contact," was itself born of English parents in 1881? Must it, like an opera singer of forty years ago, first adopt an Italian name before it will be accepted by a British public?

Already the Central London Railway Co. has given notice of an application to Parliament for powers to extend westward and eastward; every week now some new underground electric railway scheme blossoms forth for London, while in a few years electric tramways will doubtless be a common method of conveyance in this city. An urgent question, therefore, that London must ask itself *to-day* is—Does it want to preserve its gas and water pipes?

AGRICULTURAL DEMONSTRATION AND EXPERIMENT.

THE issue by the Board of Agriculture of the "Annual Report on the Distribution of Grants for Agricultural Education and Research in the year 1899–1900," directs attention to a department of educational activity which was practically non-existent in the beginning of the present decade. From this it need not be inferred that there was no education in agriculture—both in the class-room and on the field—before this date. The work of Rothamsted, of our leading agricultural societies, and of certain agricultural colleges, is conclusive evidence to the contrary. But it was not till some ten years ago that the aid of the State was given to the establishment and maintenance of agricultural departments in provincial colleges, and of independent teaching institutions, which should be in a position to supply education and advice to the agricultural community in their district.

The report before us summarises the courses of instruction, attendance, intra- and extra-mural work, and financial aspects of each of the eleven English and Welsh collegiate departments and teaching institutions that divide amongst them 7750*l.* of the Board's grants. The grants to Scotland have, since 1896, been paid through the Scotch Education Office, so that the work of North Britain does not come within the purview of the Board's report.

Within certain limits, each institution is allowed to administer its grant and organise its work on the lines that experience has shown to be most consistent with local requirements. As a result, we find considerable variety in the educational ramifications of the different centres, though this variety is less pronounced now than formerly. Practically all the colleges receiving the Board's grants have arranged courses of instruction, extending over two or three years, which lead up to a certificate, diploma or degree. In addition to these extended courses, most of the colleges are now holding short courses of six to ten weeks, which are specially designed to meet the wants of young farmers who cannot be spared from home for a longer period. Such classes have proved most useful in America and on the Continent, and they are also being well attended in this country.

A prominent feature of the work of all the colleges is the conduct of field demonstrations and experiments, of which a condensed account is given in the second section of the appendix of the Report under notice. This form of educational work was vigorously prosecuted by Young and Marshall in the latter half of last century, and, in the face of a mild undercurrent of opposition, it has been continued ever since. It is a form of educational activity that has been largely developed in the United States, in Canada and on the Continent, so that it may fairly be urged that, whatever its weaknesses, it has, on the whole, gained extensive adoption by reason of intrinsic merit. The objectors to this form of education, or means of agricultural improvement, base their opposition on the following grounds:—

(1) The difficulty of getting a series of plots on soil of equal quality.

(2) The danger of applying results obtained on one farm to the agricultural practice of another.

(3) The possible interference with results of extraneous causes, *e.g.*, birds, mammals, insects, diseases, weather.

(4) The misinterpretation of the value of purely quantitative results.

No doubt the usefulness of field trials may be marred, or worse, by failure under these heads, but the exercise of ordinary care in selecting the land, the rejection of results that have manifestly been unduly influenced by extraneous causes, and, above all, the frequent repetition, both as regards place and season, of the experiments, must in the end furnish a set of figures that cannot fail to prove a useful guide in agricultural practice. If one may not indulge in wide generalisation from even a considerable number of concrete cases, that is no valid argument against field trials. On the contrary, it is fair to say that if there are a large number of soils that require special treatment, it is the more necessary that farmers should be made familiar with the arrangements and method of field trials, in order that they may, by their aid, inquire into the manurial and other requirements of their own land. In point of fact it is probable that therein lies the main value of such work. No one, who has given careful heed to the experimental results of past years, will deny that, at least under certain conditions of soil, some very striking and unexpected results have been obtained. Farmers who see such results, recognise that they have made the acquaintance of facts that they would not have anticipated, and they naturally conclude, and rightly, that if the unexpected has

happened on the farm of a neighbour, it may be that their own practice is not all that could be desired. When once this spirit of inquiry has been roused, a long step forward has been made. But farmers will give attention to work that is going on in their own neighbourhood, under conditions with which they are familiar, when they would not concern themselves with results obtained on a station that they had never seen. For this reason, local experiments and demonstrations would be justified, even if they were no more than a repetition of work conducted elsewhere.

Some curious results have, from time to time, been got with potash, and at no place has this been more conspicuously the case than at the Northumberland Demonstration Farm of Cockle Park. Speaking generally, and taking the average of several seasons, one finds that, in the North of England, the addition of 3 or 4 cwt. of kainit per acre to a nitrogenous-phosphatic artificial dressing increases the turnip or swede crop by about 30 cwt. per acre. Such a return is moderately profitable, but not sufficiently so to make it a matter of the first importance, whether north-country farmers use potash for their turnips or not. But not so at Cockle Park, where the arable land is a light loam overlying millstone grit. At that station, potash has proved to be absolutely indispensable in the growth of root crops, so much so, in fact, that, without the support of potash, other manurial elements have practically no effect. The figures for turnips—in terms of an acre—for three years are as follows:—

Treatment of crop.	1896		1897		1898	
	Tons.	Cwt.	Tons.	Cwt.	Tons.	Cwt.
Unmanured	19	19	2	10	13	2
Nitrogen and phosphoric acid, no potash	16	17	4	17	8	3
Nitrogen and phosphoric acid, with potash	26	3	14	10	25	5

During two of the seasons the crop was actually injured by the use of nitrogen (in the form of sulphate of ammonia) and phosphoric acid (in the form of superphosphate of lime) unsupported by potash. Similar results have been got by at least one foreign investigator by means of water-cultures, and it would be interesting to have an explanation of this curious phenomenon. But, without any explanation, the many hundreds of farmers who have seen these demonstrations have at once perceived that, on land of this character, large expenditure on manures may be absolutely profitless; and they have gone home with the determination to experiment on their own land, in order to ascertain whether their system of manuring is as rational as it might be.

To show how unsafe it is to apply, generally, results obtained with one class of plant, attention may be directed to some experiments begun in 1897 on a permanent meadow, situated within a few hundred yards of the three fields in which the turnip experiments were conducted. The soil of this meadow is somewhat more argillaceous than that of the arable land, but from the appearance of the soil, and in view of the results referred to above, one would not expect that the herbage growing upon it would be absolutely independent of artificial supplies of potash. And yet four years' results have shown that not only does potash fail to increase the yield, but that, when used unsupported by phosphate, it does positive harm. The figures are as follows, the sulphate of potash, which was applied each year, supplying 50 lbs. of potash per acre:—

Treatment.	1897	1898	1899	1900	Total
	Cwt.	Cwt.	Cwt.	Cwt.	Cwt.
Unmanured	22½	27½	19½	20	89½
Potash only	20	25½	13¾	16¾	76
Sulphate of ammonia	33½	37¼	25	26½	122¼
,, ,, plus potash	29¾	35¼	19	22¾	106¾
Phosphate	25	32¼	23¼	27	107½
,, plus potash	26¼	36¼	20½	26½	109½
Ammonia and phosphate	35¼	41½	26¼	30½	133½
,, ,, plus potash	33½	41	24¼	30½	129¼

Without any exception, the potash has invariably reduced the yield (*a*) when used alone, and (*b*) when added to a nitrogenous manure. This depressing influence is more pronounced in the last two than in the first two years, a result doubtless due to the accumulation of potash in the soil. When used along with phosphate, the potash slightly increased the yield in the first two years, whereas it has reduced it in the last two. Finally, when added to both nitrogen and phosphate, the action of the potash has either been harmful, or, at the best, negative.

These results not only come out in weighing the crops, but they are precisely what one would anticipate from the general appearance of the plants. In the case of turnips, the plants that have received no potash are of an unhealthy green colour. The leaves are shrivelled and puckered, and covered by large yellow blotches. In the case of the meadow plots that have received potash, *without phosphates*, the herbage is pale, almost brownish-green in colour. In other parts of the country this poisonous influence of potash on the mixed herbage of meadows has been observed, Mr. Wood, for instance, having recorded several cases in the east of England. It is evidently a subject of some scientific interest, and worthy of further investigation.

In the past, the agricultural experiments and demonstrations conducted by the local colleges and other institutions subsidised by the Board of Agriculture have been chiefly concerned with the manuring of land, though a considerable amount of work has, in the aggregate, been done in the direction of (*a*) testing new varieties of plants; (*b*) dealing with insect and fungoid injuries, and the eradication of weeds, notably charlock; (*c*) the rearing and feeding of stock; (*d*) dairying; (*e*) cider manufacture. The initiation of such work has, with few exceptions, been left entirely in the hands of the staff at the various centres, and while much is to be said in favour of this system, there is a good deal to be urged against it. More particularly it is apparent that the lack of any central control, or, it may be, the want of opportunities for consultation among the workers, has engendered a certain amount of unnecessary confusion, which could easily have been avoided with advantage to every one. While one worker uses 50 lbs. of phosphoric acid, another, perhaps, uses 65 lbs., while a third may use 3 cwt. of some phosphate without regard to its contents of phosphoric acid. This means all-round waste of energy, and renders definite comparison of the results impossible.

By voluntary association, one special four-course rotation experiment is being carried out by the Durham College of Science, the Yorkshire College, Cambridge University, the South-Eastern Agricultural College and Nottingham University College. The present season will see the close of this experiment at three of the centres, and the results are likely to be much more valuable than if the work had been entirely uncoordinated. Major Craigie, in his report, directs special attention to this experiment, as also to the fact that the Board has

made arrangements for the repetition in the south and centre of England of the Northumberland "manuring for mutton" experiment. This work, started in the spring of 1897, took the form of determining the results of the manurial treatment of grass land, not in terms of hay, but in the terms of live-weight increase. Ten three-acre plots were fenced off on a large field of poor pasture, and nine of these plots were subjected to as many distinct forms of treatment. The plots have each year been grazed by sheep, each plot being stocked with as many animals as a committee of practical farmers considered it would carry. The individual weights of the animals are determined by monthly weighings. During the first season (1897) variations in the yield of animal increase were fairly pronounced; while in the second, third and fourth years the results have been extremely striking. Lime, used alone, has almost failed to act; while phosphates, especially basic slag, have, in some cases, enabled the land to carry twice as many sheep as the untreated area, and not only so, but the animals have given more than double the individual live-weight increase. The addition of sulphate of ammonia or potash to a phosphatic dressing has had extremely little influence, whereas the beneficial effects of a similar addition of pulverised lime have been very conspicuous. The yield of hay on separate sub-plots gave but a modified reflection of the mutton results, showing that the manures have had much more influence on the quality than on the quantity of the herbage. By a single expenditure of about twenty shillings per acre on manure, it has been shown that land worth five shillings per acre per annum has been—temporarily at least—raised in value to five or six times this sum. Whether such a result will be obtained in other parts of the country it would be hazardous to predict, but there can be no question of the desirability of putting the matter to the test, and it is satisfactory to find that the Board has made arrangements to do so.

The past ten years may be regarded as a period of adjustment in the history of the provincial agricultural colleges. They were called into being as a result of the sudden endowment of county councils with large funds, and practically no preparations had been made for their reception. They were placed in the receipt of grants from public bodies, and these bodies naturally wanted results for their money. If these results could be made to loom large in the eyes of the county council electorate, so much the better. The success of a local lecture was judged rather by the size of the audience than by any educational standard. The county councils vied with each other as to the number of field demonstrations they could show. But things are different now. Both colleges and county councils have elaborated educational schemes, and work will in the future be tested by its intrinsic quality. Now that the feverish incentive to the production of results has been replaced by a demand for thoroughness, it is to be hoped that the colleges will be allowed to settle down to do some first-class work. But, with the best intentions, county councils sometimes handicap the staff of the institutions that they support. It is quite impossible that a department of agriculture can develop in such a way as to do justice to its students, or to take its proper place amongst the other departments of a college or University if a large portion of the time of the members of its staff has to be spent away from headquarters. The local work that they are doing may be of the greatest importance, but the time occupied in its preparation and accomplishment makes a serious inroad on the efficiency of in-college work. It is to be hoped that county councils will give their support to central institutions without being too exacting in their local demands upon them, while the Board of Agriculture should be endowed with funds sufficient to enable the agricultural departments of the colleges to prosecute the highest forms of research.

WM. SOMERVILLE.

HORTICULTURAL PRACTICE.

ONE method by which the gardener "improves" particular plants was well illustrated at the Hybridisation Conference held in the gardens of the Royal Horticultural Society last year. The proceedings of that meeting were amply recorded in these columns at the time, so that there is no need to do more than mention that branch of the subject. Another method of improvement consists in the continuous selection of the best and the cotemporaneous elimination of inferior varieties. This is the method followed by the great seed-firms, who devote large areas to their trial grounds and take the greatest pains to secure and maintain the purity of their stocks. A variation may arise from seed or from "sports," the latter term being applied to bud-variations which occur suddenly, no one knows why. If the variation be a desirable one, the cultivator preserves the seed, sows it, and in due time finds that a certain percentage of the seedlings reproduces the desired form. Further sowings take place, the percentage of the new variation being constantly increased till at length the seeds are said "to come true," and a new species, at any rate so far as gardens are concerned, is evolved by the constant practice of selection.

In the case of a sport, propagation is effected by cuttings or grafts.

The advent of the Chrysanthemum season reminds us of other practices which the gardener adopts with the view of securing "improvement." Those who visited the recent exhibitions at the Royal Horticultural Society and at the Westminster Aquarium must have been forcibly struck with the contrast between the wild Chinese Chrysanthemum and the Japanese varieties, which constituted the essential part of the exhibition. The wild plant, sent from the Royal Gardens, Kew, was discovered in central China. Horticulturally it was but a poor weed, with small yellow flower-heads about half an inch in diameter, by no means so attractive as our own corn-marigold. Yet from this plant, either alone or when crossed with another species, the Chinese and the Japanese have evolved flowers of every shade of colour except blue, and the gardener has produced flowers 15 and 18 inches in diameter.

The Japanese varieties, originally introduced by Fortune in 1862, at once attracted attention by their large size and fantastic form. It is these Japanese varieties that now constitute the staple of our exhibitions, and their size and colour offer, as we have said, the greatest possible contrast to the inconspicuous flowers of the wild plant. They are purely artificial productions, and nothing like them occurs in nature, although occasionally, in Composites, malformations occur in the ray-florets which give a clue to the origin of these strange productions.

It is mainly to the art of the gardener that we owe these monstrous blooms. That art consists essentially in "disbudding" or in removing certain buds and leaving others. As the history is interesting and not generally known in scientific circles, it may be well briefly to summarise the facts of the case. The "first break" or lateral bud of a Chrysanthemum makes its appearance from the middle of April to the middle of June, the precise period differing in the case of different varieties. The second or "crown" bud appears in August, and consists of a flower-bud surrounded by leafy shoots, which grow sympodially; these are removed, and the development of the central flower-bud allowed to proceed. The third or "terminal" bud is formed in September, and always consists of one central bud surrounded by other secondary flower-buds, but not by any leaf-shoots. The secondary flower-buds are removed, and all the energy of the plant concentrated in the central bud, which, in florists' language, is "taken," or, more correctly, which is reserved.

Lastly, in December, after the flowers are over, a quantity of leaf-buds are produced from the base of the stem. These are used as cuttings.

Dis-budding is a common enough procedure in roses and other flowers grown for exhibition; but the peculiarity in the Chrysanthemum is the difference in the position, time of formation, and nature of the buds. The practice varies in accordance with these differences. Different varieties demand different treatment. In some instances the bud must be "taken" at this time, in other cases at a different period. In some varieties the best blooms are produced by the "crown" buds; in others it is the terminal buds that produce the finest flowers. All this is determined by experiment, but in any case this variation in the position, form and time of development of the buds is sufficiently important to attract the attention of the physiologist.

Another practice now much followed is that of retarding the growing and flowering period of plants by means of cold. By this means flowers, say of lily of the valley, can be had at any season that may be desired.

The chief point of physiological interest appears to reside in the fact that plants can be subjected without injury to much lower degrees of cold than was formerly supposed.

SOME REMARKABLE EARTHQUAKE EFFECTS.

MR. R. D. OLDHAM'S elaborate report on the great earthquake of June 12, 1897, published in the *Memoirs* of the Geological Survey of India (vol. xxix.), has been referred to on several occasions in these columns; and an abstract has been given of its most important contents (vol. lxii. p. 305, July 26, 1900). There are many striking illustrations of earthquake effects in the report, and three of the plates are here reproduced.

That pillars and other similar objects may be left standing, but with one part twisted round upon another, has long been known as a fantastic effect of severe earthquakes, and even in some cases of earthquakes which can scarcely be called severe. There is, however, no instance where cases of this kind were so numerous, and so various in the nature of the object rotated, as the Indian earthquake. The most imposing and striking of the many instances of twisting found by Mr. Oldham is that of the monument to George Inglis, erected in 1850 at Chhatak. This conspicuous landmark takes the form of an obelisk, and, rising from a base 12 feet square, must have been over 60 feet high before the earthquake. It is built of broad, flat bricks, or tiles, laid in mortar and plastered over, and is represented in its present state in Fig. 1. About 6 feet of the monument was broken off and fell to the south, and 9 feet to the east. Of the remainder, the top 20 feet was separated at a height of about 23 feet from the ground, and twisted in the opposite direction to that of the hands of a watch lying face upwards on the ground.

The view in Fig. 2 shows some tombs in the cemetery at Cherrapunji. All the tombs are of the oblong form with sloping tops, and are built of rubble stone masonry. Few are broken up, but nearly all have sunk down into the loose sand beneath them, and are leaning over at various angles to the north. The cemetery is situated on the top of one of the small knolls of sandstone which are scattered over the Cherra plateau. This sandstone originally rested upon the limestone of the plateau, which has been dissolved away from beneath it, and is accordingly much broken. The earthquake seems to have shaken the surface down into a perfect quicksand, into which the tombs sank.

A direct measure of the amplitude of the earth-wave, or of the greatest movement of the wave particle backward and forward, was obtained at Cherrapunji. Mr. Oldham concludes, from observations of the length of a depression scooped out by the movement of the ground against some tombs which remained stationary, that the extreme range of motion cannot have been less than ten inches, may have been as much as eighteen inches, and was probably about fourteen inches. The amplitude or range of the wave particle on either side of its original position would be half these amounts.

FIG 1.—Monument at Chhatak, with part twisted by earthquake. The part of the monument left standing is about 46 feet high.

The banks of the Brahmaputra are fissured at intervals on each side along a length of 260 miles, and fissures extend along the banks of all the minor branches of the river and its tributaries within the disturbed area. As a rule, the fissures run parallel to the bank of the river, and where this is not the case, some peculiarity in the contour of the ground—a drop, for instance, from a higher to a lower level—can usually be found to account for the

FIG. 2.—Tombs in cemetery, Cherrapunji.

change of direction. At Rowmari, for instance, besides the fissures parallel to the bank of the Brahmaputra, which here runs nearly north-east and south-west, a large fissure runs to the south-east at right angles to the river bank for a distance of at least 500 yards, where it becomes lost in a jheel, and is said to be traceable for a distance of nine miles. Sand and mud were ejected from the fissure to a depth of at least four feet. Other fissures

FIG. 3.—Fissure at Rowmari.

branch off from this. Subsequent to the ejection of the sand, the surface sank down to a depth proportional to the amount of material ejected, and several crater-like hollows were formed as the water drained back into the fissure. Illustrations of this and many other effects are given by Mr. Oldham, and his complete report upon the Indian earthquake, in all its scientific aspects, is a memoir which will take its place among classical papers on seismology.

INVESTIGATIONS OF THE HABITS AND FOLK LORE OF AUSTRALIAN ABORIGINES.

EARLY in the summer a memorial was submitted to the Governments of South Australia and Victoria praying that facilities might be granted to Mr. Gillen, one of the inspectors of aborigines, and Prof. Baldwin Spencer for the continuance of their investigations into the habits and folk-lore of the natives of Central Australia and the Northern Territory. The memorial, which was signed by all British anthropologists and many prominent representatives of other sciences, has met with a prompt and generous response. The Government of South Australia has granted a year's leave of absence to Mr. Gillen, and the Government of Victoria has provided a substitute for Prof. Spencer during his absence from Melbourne. Mr. Syme, the proprietor of the Melbourne *Age*, has contributed 1000*l.* towards the ordinary expenses of the expedition. The Government of South Australia has also allowed the expedition to make use of the depôts and staff of the Transaustralian telegraph for the forwarding and storage of supplies. The explorers start in February, and it may be confidently anticipated that, if the winter rains make conditions favourable for travelling, they will be rewarded with the same conspicuous success which attended their expedition of three years ago; although the task before them requires even greater tact, since the natives of the Northern Territory are more difficult to deal with than the aborigines of the centre, who know Mr Gillen and regard him with the utmost confidence. The tribes of the MacDonnell Ranges will be studied even more minutely than before, and afterwards the explorers will go towards the Gulf of Carpentaria, along the Roper River, and, time permitting, proceed down the Daly and Victoria Rivers.

To quote from the *Adelaide Advertiser* of October 4, "It scarcely needs a scientific mind to appreciate the value of the task which Messrs. Gillen and Spencer are about to renew, and possibly complete. The mystery their labours will contribute to unveil may well captivate the fancy of the most unlearned 'man in the street.' . . . The breath of the white man has scorched out of existence so many aboriginal races and tribes that civilisation may be thankful that there are still untutored savages left to throw light on its own beginnings."

NOTES.

SIR JOSEPH HOOKER has been elected a Foreign Associate of the Paris Academy of Sciences.

THE death is announced of Prof. G. F. Armstrong, Regius professor of engineering at Edinburgh University since 1885.

THE death is announced of the Rev. Father Armand David, Correspondant of the Paris Academy of Sciences, in the Section of Geography and Navigation.

WE learn from the *Athenaeum* that the Amsterdam Society for the Advancement of Medical and Natural Science has conferred its Swammerdam Medal upon Prof. Carl Gegenbauer, of Heidelberg.

DR. HERMAN S. DAVIS, recently expert computer of the U. S. Coast Survey, has been appointed observer at the International Latitude Observatory at Gaithersburg, Maryland, one of the six stations established by the Centralbureau der Internationalen Erdmessung for an investigation of variations of latitude.

WE are asked to announce that the Thomson Foundation Medal of the Royal Geographical Society of Australasia will be awarded to the author of the best original paper on each of the following subjects:—(1) The commercial development, expansion and potentialities of Australia—or, briefly put, the commerce of Australia. To be sent in not later than October 15, 1901. (2) The pastoral industry of Australia, past, present and probable future. To be sent in not later than June 15, 1902.

THE College of Physicians of Philadelphia announces that the next award of the Alvarenga Prize, being the income for one year of the bequest of the late Señor Alvarenga, amounting to about 180 dollars (36*l.*), will be made on July 14, 1901, provided that an essay deemed by the Committee to be worthy of the prize shall have been offered. Essays intended for competition may be upon any subject in medicine, but must be unpublished. They must be received by the secretary of the college on or before May 1, 1901. The Alvarenga Prize for 1900 has been awarded to Dr. David de Beck, of Cincinnati, Ohio, for his essay entitled "Malarial Diseases of the Eye."

We learn from *Science* that the New York Board of Health is building, at a cost of 4000*l.*, a laboratory to be wholly devoted to the study of the bubonic plague. Special care will be taken in its construction. The ground floor will be occupied chiefly with eight stalls for horses that will supply the anti-plague serum. A staircase from the outside will lead to the upper floor, where experiments will be carried on. The walls and floor are to be of steel and cement, so as to be rat proof, and the windows are to be especially screened to keep out flies and mosquitoes.

IT will be remembered that shortly after the death of the late Mr. G. J. Symons, F.R.S., the founder of the British Rainfall organisation, a movement was started for the foundation of a memorial to him. It was resolved that the memorial should take the form of a gold medal, to be awarded from time to time by the Council of the Royal Meteorological Society for distinguished work in connection with meteorological science. The committee appointed to take the necessary steps to raise a fund for that purpose announce that the appeal has met with a hearty response from meteorologists, water engineers and other admirers of Mr. Symons's work. The fund will be open until the end of January next, and subscriptions should be sent to the treasurer, Dr. C. Theodore Williams, 70, Victoria Street, Westminster.

THE Vienna correspondent of the *Times* states that two facts of considerable importance, both to sanitary authorities and the general public, are set forth in the definitive report of the Austrian Medical Commission of the Vienna Imperial Academy of Science, sent to Bombay in 1897 to study the issue of a work on the morphology and biology of the bacillus and on artificial infection, &c. It has been prepared by Drs. Albrecht and Ghon, both surviving colleagues of Dr. Müller, who died of the plague in Vienna two years ago under melancholy circumstances reported at the time. The experiments recorded in the work now published show that certain species of animals are easily infected by rubbing the virulent matter lightly on the skin even when it is perfectly intact and free from injury. This is said to be the most frequent and important form of infection in the case of human beings. The second result of the experiments conducted in Vienna, which were forbidden after the unfortunate accident that cost the life of Dr. Müller and two other victims in 1898, has been to prove that perfect immunity can be given to the most susceptible animals against injections which would otherwise be absolutely fatal.

THE mode of infection with plague was referred to by Prof. A. Calmette in the second Harben lecture, delivered at the Examination Hall of the Royal College of Physicians and Surgeons on November 14. In the course of his lecture, Prof. Calmette said (reports the *Lancet*) that certain epidemics of plague had been remarkable for the fact that all the cases presented a primitive pneumonic form, the mode of entry having been, therefore, exclusively through the nose or mouth, while in others the infection had been produced by the skin, either following slight excoriations or bites of fleas, bugs, and other parasitical insects. During the epidemic in Portugal last year, he observed with Salimbeni a case in which the infection was through a bug-bite. Hankin and Simond, in India, had cited several examples of individuals who had contracted plague from touching diseased or dead rats. It was probable that the transmission of the plague to the man was by fleas living on the rats. Experiment in the laboratory had shown how quickly a healthy rat would contract the plague if caged with a diseased rat which was infested with fleas, while a healthy rat remained healthy when shut up with one which was diseased but was free from fleas. Whatever the mode of entry of the virus, multiplication of the plague bacillus resulted first in the lymphatic channels and then in the blood.

THERE ought to be a ready and liberal response to the appeal for contributions to establish a permanent memorial to the late Miss Mary Kingsley; for her works on the customs and institutions of the native races of West Africa are admired by a large public. A strong and representative committee has been formed, and it has been decided that, if sufficient funds are obtained, the memorial shall take the form of a small hospital, to be established in connection with the Liverpool School of Tropical Medicine, and shall also be used to institute "The Mary Kingsley Society of West Africa," to stimulate research and collect information concerning West Africa. Much information of the required kind as to West African sociology is already on record, scattered through the works of the older writers on those parts, as well as in more recent books of travel, in papers published in periodicals, in Blue-books and in official reports; and a very great deal more may still be gathered by Government officials, traders, missionaries, travellers and by the small but remarkable band of natives who are already educated. It is proposed that the "Mary Kingsley Society" should employ a trained ethnologist, both to collect and arrange in scientific form the material which is thus already on record, and to institute and direct research for further material of the same sort. Subscriptions may be assigned by the donors to either the hospital or the society, and the two funds will be kept separate. Contributions for the "Mary Kingsley Memorial Hospital" should be sent to Mr. A. H. Milne, B. 10, Exchange Buildings, Liverpool, and for the "Mary Kingsley Society of West Africa" to Mr. George Macmillan, St. Martin's Street, London, W.C.

THE U.S. Pilot Chart of the North Atlantic Ocean for November gives the longitude at which a number of vessels bound round Cape Horn crossed the latitude of 50° S. in the Atlantic and the Pacific respectively, and shows the courses followed by ships making the best and worst passages. The time occupied varied from eight to thirty days. Some of the captains kept as closely as possible to Cape Horn, while others reached the parallel of 60° S. In no other part of the world are the meteorological conditions more trying, owing to the persistency and violence of the westerly winds, the turbulence of the sea and frequent blinding squalls of hail and sleet. The Hydrographic Office has, therefore, rendered good service in pointing out the route to be followed, and the necessity of adapting it to the prevailing meteorological conditions, especially with regard to barometric pressure. A vessel fortunate enough to encounter easterly winds in rounding the Horn can only retain them as long as possible by remaining on the southern side of the low barometric pressure which they surround, instead of standing at once to the N.W., regardless of the indications of the barometer.

THE report of the Prussian Meteorological Office for the year 1899 points with satisfaction to the increased uniformity of action between all the German States as regards the methods of discussion and publication of observations, and to the tendency towards augmenting the number of observing stations where necessary. An important investigation has been carried out by Dr. Edler, at the suggestion of Dr. v. Bezold, on the influence of stray currents from electric tramways on the instruments for measuring terrestrial magnetism, with a view to determining the minimum distance to which magnetic observatories should be removed. The result shows that the observatory must be at least five miles from the line, and, for researches of a delicate nature, at least twice that distance is required. Special attention is paid to the investigation of the upper air by means of kites and balloons. Two of the unmanned balloons reached, during the year in question, about 22,000 and 26,000 feet respectively, and we learn from other sources that these important investigations are being actively carried on during the current year.

IN the *Journal* of the College of Science, Imperial University of Tokio, Prof. H. Nagaoka and Mr. K. Honda discuss the changes of volume and of length in iron, steel and nickel ovoids by magnetisation, and a separate paper by Mr. K. Honda deals with the combined effect of longitudinal and circular magnetisation on the dimensions of tubes of these metals. Among various results of the combined investigation we notice that:—(1) the transient current, as well as the longitudinal magnetisation produced, by twisting an iron or steel wire is opposite to that produced by twisting one of nickel up to moderate fields; (2) the transient current, as well as the longitudinal magnetisation produced, by twisting an iron, steel or nickel wire reaches a maximum in low fields; (3) in strong fields the direction of the current, as well as the longitudinal magnetisation, is the same in iron, steel and nickel. In alluding to this work we cannot but draw attention to the evidence of Japanese enterprise that is afforded by the publication of a journal containing scientific papers in English and German by Japanese professors and university graduates.

IN the *Philosophical Magazine* for September Dr. Sydney Young discusses the Law of Cailletet and Mathias, according to which the mean of the densities of a liquid and its saturated vapour for any stable substance is a rectilinear function of the temperature. It appears, among other results of this investigation, that the law, though approximately satisfied, is not absolutely true unless the ratio of the actual to the theoretical density at the critical point has the normal value 3·77. In most cases if the mean density be expanded in powers of the temperature, the sign of the coefficient of the second power depends on whether the ratio in question is greater or less than the normal. The coefficient of the second power is so small that the linear formula may be used to calculate the critical density from observations at temperatures above the boiling point, but the error thus introduced becomes considerable if it be required to calculate the critical density from observations of mean densities at lower temperatures; moreover, as pointed out by Guye, the law fails when the molecules differ in complexity in the liquid and gaseous states.

IN the *Journal de Physique* for September, M. E. Mathias discusses two interesting groups of loci relating to the thermodynamic properties of a liquid in presence with its saturated vapour. The first is the locus in the (p,v) plane of points, such that the volume of the liquid is equal to that of the vapour (the total mass being unity). This locus, the author finds, is a curve constantly convex towards the axis of abscissæ, and is the only one of the curves defined by the constancy of the ratio of the volumes of the liquid and vapour, which cuts the curve of saturation at a finite angle at the critical point. M. Mathias proves that the locus has no point of inflexion, but that the angular coefficient increases with the temperature. The second group discussed consists of the curves for which the masses of the liquid and vapour are constant. In accordance with Raveau's investigation, the only one of these curves which cuts the curve of saturation at a finite angle is that corresponding to equal masses of liquid and vapour.

MR. S. H. BURBURY communicates to Wiedemann's *Annalen* a reply to certain objections raised by Herr Zemplén Győző against his modifications of the Kinetic Theory of Gases. In it he gives certain amplifications of his proof of the property that the mean values of the products of velocities of neighbouring molecules of a gas are positive, and discusses the point at which his method diverges from those leading to the ordinary Boltzmann-Maxwell distribution.

THE U.S. Department of Agriculture has issued a bulletin containing records of investigations made by Mr. M. E. Jaffa, at the Agricultural Experiment Station of the University of California. A number of analyses of food materials were made, and dietary studies were conducted with a football team and with a chemist's family, as well as with a number of infants. In one instance the metabolism of nitrogen of an infant was also studied. Such investigations cannot fail to furnish aid in fixing upon dietary standards, and the proper factors to be used in computing the amounts eaten by persons of different ages as compared with an adult man.

FROM Messrs. B. O. Peirce and R. W. Wilson we have received a paper on the thermal diffusivities of different kinds of marble, published in the *Proceedings* of the American Academy of Arts and Sciences, xxxvi. 2. The tables which the authors give of the specific heats of various marbles are useful for several purposes, and the law of variation of the specific heat of dry Carrara marble with the temperature appears to be well represented by the formula $S = 0{\cdot}1844 + 0{\cdot}000379\, t^2$.

AT the last meeting of the Liverpool Geological Society, a paper was read on the carboniferous limestone of Anglesey, by the late Mr. G. H. Morton. The paper was left by the author in a finished state, and was intended by him to be the concluding portion of the series of papers on the carboniferous limestone of North Wales, on which he had been engaged for a period of nearly forty years. We are informed that, in addition to the paper itself, Mr. Morton left revised lists of fossils brought up to date with their comparative rarity or otherwise, for the districts previously described, but unfortunately the list for Anglesey was not completed, as he intended to visit one or two localities this summer to check his lists. It is intended to print the completed lists, but not the Anglesey list. Lists for certain localities in Anglesey were incorporated by Mr. Morton with his paper, which will be printed in full in the Society's *Proceedings*.

A LECTURE on the coal resources of Victoria, Australia, was delivered at the Imperial Institute, on Monday evening, by Mr. James Stirling, mining representative of the Colony. The attention of most nations is now turned to their coals. The demand to-day, owing to the rapid development of industries and extension of commerce, is greater than it has ever been before. The Australian Colonies have large areas of coal-bearing territory, and up to the present have produced a million tons of coal, the largest output having been from New South Wales. After giving a short account of the first discovery of coal in Victoria, Mr. Stirling said that about ten years ago he had been deputed to investigate the Gippsland coalfields, and he had been able to prove that within an area of 3,000 square miles of Jurassic rocks there were a number of seams of good black coal from 2 to 5 feet in thickness. But it is in brown coal that Victoria is specially rich. From borings carried on over a distance of 50 miles in the Latrobe Valley, Mr. Stirling has estimated that there cannot be less than 31,144,400,000 tons of brown coal. In several places shafts had been sunk through beds of from 20 to 200 feet thick, and at one place a coal bed, 70 feet thick, is being worked as a quarry by open face. Various analyses of these coals have shown them to be superior to the average German brown coal, and to have a much smaller percentage of ash. Austria, Germany and Italy have put their smaller deposits of this coal to commercial uses by compressing it into briquettes, distilling oils, etc., and the same could be done in Victoria, besides converting the fuel directly into electrical energy.

THE Geological Survey has published the second part of "The Geology of the South Wales Coal-field," in which the country around Abergavenny, included in the new series map, No. 232, is described by Messrs. A. Strahan and W. Gibson. A study of

the northern part of the Usk inlier of Silurian rocks confirms the opinion that a well-defined plane of division separates these strata from the Old Red Sandstone. A small portion of the Black Mountains, with the Old Red Sandstone Sugar Loaf, and the fine escarpment of the Blorenge, formed of Old Red Sandstone and Lower Carboniferous rocks, come in for description, to which Mr. J. R. Dakyns contributes. The Carboniferous Limestone displays the phenomenon of dolomitisation with unusual clearness, and notes on microscopic sections of the rock are contributed by Prof. W. W. Watts. Special attention is naturally given to the Coal-measures, and it is pointed out that while the coals are more extensively worked than formerly, the iron-ores are now hardly worked at all. The Glacial Drifts present many features of interest, notably in the case of a transported mass of Carboniferous grit, which forms a small hill upwards of 200 yards in length, and rests on Boulder Clay.

IN the October issue of the *American Naturalist*, Prof. H. F. Osborn reconsiders the evidence in favour of the existence in the Permian of a common ancestral stem from which have diverged dinosaurs and birds. It is argued that many of the resemblances between these groups are adaptive rather than genetic, while the apparent close correspondence in the structure of the pelvis between adult birds and the herbivorous dinosaurs (which are specialised types) is due in a considerable degree to a misinterpretation of the homology of some of their elements. Nevertheless, the resemblances between the two groups are so numerous as to justify the belief of kinship. And special importance attaches to the opinion that some sort of bipedalism was a common character of all dinosaurs, the suggestion being countenanced that certain forms, like Stegosaurus, have reverted from a bipedal to a quadrupedal mode of progression. Our present knowledge, therefore, justifies us in saying that "in this bipedal transition, with its tendency to form the tibiotarsus, the avian phylum may have been given off from the dinosaurian. This form of the Huxleyan hypothesis seems more probable than that the avian phylum should have originated quite independently from a quadrupedal proganosaurian reptile, because the numerous parallelisms and resemblances in dinosaur and bird structure, while quite independently evolved, could thus be traced back to a potentially similar inheritance."

VOLUME II., part 3, of the *Annals* of the South African Museum is occupied by the continuation of Sir George Hampson's synopsis of the moths of South Africa.

THE interest attaching to the great skua gull, on account of its narrow escape from extermination in the Shetlands, will cause many ornithologists to hail with satisfaction the account of its habits in the southern hemisphere, published by Mr. R. Hall in the October number of the *Victorian Naturalist*. The extent of the geographical range of this bird—from the Shetland Islands past Kerguelen's Land to New Zealand, and sparingly between the Cape of Good Hope, Ceylon and Southern Australia—is very remarkable.

THE latest issue of the *Morphologisches Jahrbuch* (vol. xxix. part 1) contains the results of an elaborate investigation by Dr. O. Grosser into the anatomical structure of the nasal cavity and throat of the species of bats indigenous to Germany. In the same number Prof. L. Balk describes and figures a human vertebral column presenting the rare abnormality of only six (instead of seven) cervical vertebræ. The comparative anatomy of the eye-muscles forms the subject of a communication by Herr H. K. Corning; while the nature of the partition between the pericardiac and peritoneal cavities engages the attention of Herr F. Hochstetter.

THE first three parts of a lavishly illustrated work on the "Living Races of Mankind" have been published by Messrs. Hutchinson and Co. The work is by the Rev. H. N. Hutchinson, the author of "Extinct Monsters" and other works of popular natural science, assisted by Prof. J. W. Gregory and Mr. R. Lydekker, F.R.S. There will be eighteen parts, published at fortnightly intervals, and when complete the work will be an attractive, as well as instructive, account of the customs, habits, pursuits, feasts, and ceremonies of the peoples of the world. Much care and trouble have been expended in collecting the photographs to illustrate the text, and it is to be hoped that the enterprise will meet with success. It is highly important that the British public should be interested in the study of ethnology, and the work now in course of publication will assist in attaining this end.

A FEW weeks ago Sir William White, the president of the Institution of Mechanical Engineers, brought before the Institution a letter from the Association of German Engineers suggesting that scientific and technical societies in the United States, France, Germany and England should unite in the preparation of an English, French and German technical dictionary. It was decided not to officially take part in the scheme, but the members of the Institution were invited to assist in the work. We are reminded of this by the appearance of the second volume of a "Practical Dictionary of Electrical Engineering and Chemistry, in German, English and Spanish," by Mr. Paul Heyne, which has just been received from Messrs. H. Grevel and Co. The dictionary is published in three volumes, one with German words alphabetically arranged, and their English and Spanish equivalents in parallel columns, and the two other volumes with English and Spanish words alphabetically arranged. The dictionary should be of value in manufactories and business houses concerned with engineering work.

THE second volume of "A Hand-List of the Genera and Species of Birds," by Mr. R. Bowdler Sharpe, has been issued by the Trustees of the British Museum. This volume contains the parrots and those birds commonly known as "Picarians," thus leaving the Passerines for the third volume. We propose to postpone a detailed notice of this useful work till the issue of the last volume.

THE additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mr. D. Nagle; a Barbary Ape (*Macacus inuus*) from North Africa, presented by Mr. Thomas Pink; a Common Squirrel (*Sciurus vulgaris*), British, presented by Mr. C. W. Labarte; two Black Kites (*Milvus migrans*) from East Africa, presented by Mr. Campbell Hansburg; two Auriculated Doves (*Zenaida auriculata*) from South America, presented by Mrs. Aston; a Redbreast (*Erithacus rubecula*), British, presented by Canon Wilberforce; a Common Fox (*Canis vulpes*), British, presented by Mr. W. B. Spiers; a Horned Lizard (*Phrynosoma cornutum*) from California, presented by Mr. H. L. Brackenbury; a Common Chameleon (*Chamaeleon vulgaris*) from North Africa, presented by Mr. Small; two Brown Hyænas (*Hyaena brunneus*, ♂ ♀) from South Africa, a Common Wolf (*Canis lupus*, white var.), European, a Crab-eating Raccoon (*Procyon cancrivorus*) from South America two Rosy Parrakeets (*Palaeornis rosa*, ♂ ♀) from Burmah, two Vernal Hanging Parrakeets (*Loriculus vernalis*) from the East Indies, a Malabar Mynah (*Poliopsar malabaricus* from Hindostan, a Grey Monitor (*Varanus griseus*) from North Africa, three Giant Toads (*Bufo marinus*) from South America, deposited; an Indian Cobra (*Naia tripudians*) from the East Indies, purchased.

OUR ASTRONOMICAL COLUMN.

THE LEONID METEORS.—As was anticipated, the Leonid meteors failed to appear in any numbers last week. In a letter to the *Times*, Mr. W. H. M. Christie, the Astronomer Royal, states that a watch was kept at the Royal Observatory on the nights of November 13–14, 14–15 and 15–16, but comparatively few Leonids were seen. The following is a statement of the number of meteors noted by three observers on the three nights in question:—

	Length of watch.	Total number of meteors.	Number of Leonids.
November 13–14	5 hours	25	5
,, 14–15	2 ,,	20	6
,, 15–16	4½ ,,	55	23

It will be seen that there was nothing in the nature of a shower of Leonids.

Mr. E. C. Willis, writing from Norwich, says:—"Watches for the Leonids were first undertaken on the morning of November 10, and continued at various intervals until the evening of November 16. The total duration of the actual watches was 12¼ hours, but a considerable portion of this time was more or less cloudy, and the moon was above the horizon nearly the whole of it. The total number of Leonids recorded was 42, while the other meteors numbered 110. No Leonids were observed before the morning of November 11, or after the morning of November 16, and although it is no doubt very possible that the shower may have extended over a much longer period, it is certain that in that case it must have been of a very weak character.

"To determine the true maximum of the shower, it is necessary to combine the records of observers from various parts of the earth's surface, so as to obtain a continuous record. The maximum, however, as deduced from my own observations only, decidedly occurred on the morning of November 14. On this occasion the Leonids numbered about two-thirds of all the meteors seen, while on every other occasion they were decidedly in the minority. The hourly rate was about thirteen, but it is evident that many more would have been seen if the conditions had been more favourable, as hardly any of those observed were of less than the second magnitude. This portion of the shower seems to have ended a little before 17h. 30m., as between that time and 18h. none were observed.

"Perhaps the most remarkable point brought out by the observations was the extraordinary paucity of Leonids on the night of November 15. Watches were kept for 2¼ hours at various times between 11h. 15m. and 16h. 15m. In all, 32 meteors were seen, but only two of these were Leonids."

Prof. J. P. O'Reilly, of Dublin, informs us that on November 13, at about 5.51 p.m., he observed "a shooting star of much brilliancy, which seemed to start from about the Pleiades and to shoot in the direction of the south in a rising direction of about 25° to 30° with the horizon, and being visible over an arc of about 12° to 15°."

Balloon ascents were made from Paris on the nights of November 14, 15 and 16, but only a few stray meteors were seen.

ELEMENTS OF COMET 1900*b* (BORRELLY-BROOKS).—Prof. C. D. Perrine gives the following computed elements of this comet in the *Astronomical Journal*, No. 484, vol. xxi.:—

T = 1900 August 3d. ·20726 G.M.T.

$$\left.\begin{array}{l}\omega = 12^\circ\ 26'\ 13''\cdot2 \\ \Omega = 328\ \ 0\ \ 30\cdot1 \\ \iota = 62\ \ 30\ \ 46\cdot3\end{array}\right\}1900\cdot0$$

$$\log. q = 0\cdot006390$$

NEW VARIABLE STAR IN LYRA.—Mr. A. Stanley Williams has detected another small variable in Lyra, and in the *Astronomische Nachrichten*, Bd. 153, No. 3671, gives the following co-ordinates for its position:—

$$\left.\begin{array}{l}\text{R.A.} = 18\text{h. } 54\text{m. } 22\text{s.} \\ \text{Decl.} = +34^\circ\ 45'\cdot5\end{array}\right\}(1855\cdot0).$$

The variation in brightness, as measured from photographs taken with a 4·4 inch portrait lens during the period 1899 September 2 to 1900 October 21, is from 9·3 to 11·0 magnitude. No regular series of observations are given, but the period would appear to be about thirty days.

VISUAL OBSERVATION OF CAPELLA (α-AURIGÆ).—Prof. W. W. Campbell having some time ago discovered that this star was a spectroscopic binary with a period of 104 days, and the discussion of its parallax with the calculated dimensions of the orbit suggesting the possibility that it might be seen as a visual double star, Prof. W. J. Hussey has made a number of careful examinations of it with the 36-inch Lick telescope. In the *Astronomical Journal*, No. 484, vol. xxi, he furnishes the result of his observations. From the spectroscopic results it was indicated that the most favourable dates of observation would be April 15, June 6 and July 28, as at these times the components would be at their maximum separation. During these observations no evidence of the duplicity of the star could be detected. On August 2 and 5 further examination was made, using powers of 1000, 1500, 1900 and 2600. With all powers the star image appeared round. The "seeing" on these latter days was excellent, and it is considered that any elongation of the image as great as the tenth of a second of arc would have been perceptible even with the lowest power. On one occasion colour screens of various shades were used to reduce the light, but the result was exactly as before.

HUXLEY'S LIFE AND WORK.[1]

I ACCEPTED with pleasure the invitation of your Council to deliver the first Huxley lecture, not only on account of my affection and admiration for him and my long friendship, but it seemed also especially appropriate as I was associated with him in the foundation of this Society. He was President of the Ethnological Society, and when it was fused with the Anthropological we, many of us, felt that Huxley ought to be the first President of the new Institute. No one certainly did so more strongly than your first President, and I only accepted the honour when we found that it was impossible to secure him.

But the foundation of our Institute was only one of the occasions on which we worked together.

Like him, but, of course, far less effectively, from the date of the appearance of "The Origin of Species," I stood by Darwin and did my best to fight the battle of truth against the torrent of ignorance and abuse which were directed against him. Sir J. Hooker and I stood by Huxley's side and spoke up for Natural Selection in the great Oxford debate of 1860. In the same year we became co-editors of the *Natural History Review*.

Another small society in which I was closely associated with Huxley for many years was the X Club. The other members were George Busk, secretary of the Linnean Society; Edward Frankland, president of the Chemical Society; T. A. Hirst; head of the Royal Naval College at Greenwich, Sir Joseph Hooker; Herbert Spencer; W. Spottiswoode, president of the Royal Society; and Tyndall. It was started in 1864, and nearly nineteen years passed before we had a single loss—that of Spottiswoode; and Hooker, Spencer and I are now, alas! the only remaining members. We used to dine together once a month, except in July, August and September. There were no papers or formal discussions, but the idea was to secure more frequent meetings of a few friends who were bound together by common interests and aims, and strong feelings of personal affection. It has never been formally dissolved, but the last meeting was in 1893.

In 1869 the Metaphysical Society, of which I shall have something more to say later on, was started.

From 1870 to 1875 I was sitting with Huxley on the late Duke of Devonshire's Commission on Scientific Instruction; we had innumerable meetings, and we made many recommendations which are being by degrees adopted.

I had also the pleasure of spending some delightful holidays with him in Switzerland, in Brittany, and in various parts of England. Lastly, I sat by his side in the Sheldonian Theatre at the British Assocation meeting at Oxford, during Lord Salisbury's address, to which I listened with all the more interest knowing that he was to second the vote of thanks, and wondering how he would do it. At one passage we looked at one another, and he whispered to me, "Oh, my dear Lubbock, how I wish we were going to discuss the address in Section D instead of here!" Not, indeed, that he would have omitted any part of his speech, but there were other portions of the address which he would

1 The first "Huxley Memorial Lecture" of the Anthropological Institute, delivered on November 13, by the Rt. Hon. Lord Avebury, F.R.S., D.C.L., LL.D.

have been glad to have criticised. I was therefore for many years in close and intimate association with him.

Huxley showed from early youth a determination, in the words of Jean Paul Richter, "to make the most that was possible out of the stuff," and this was a great deal, for the material was excellent. He took the wise advice to consume more oil than wine, and, what is better even than midnight oil, he made the most of the sweet morning air.

In his youth he was a voracious reader, and devoured everything he could lay his hand on, from the Bible to Hamilton's "Essay on the Philosophy of the Unconditioned." He tells us of himself that when he was a mere boy he had a perverse tendency to think when he ought to have been playing.

Considering how preeminent he was as a naturalist, it is rather surprising to hear, as he has himself told us, that his own desire was to be a mechanical engineer. "The only part," he said, "of my professional course which really and deeply interested me was physiology, which is the mechanical engineering of living machines; and, notwithstanding that natural science has been my proper business, I am afraid there is very little of the genuine naturalist in me; I never collected anything, and species work was a burden to me. What I cared for was the architectural and engineering part of the business; the working out the wonderful unity of plan in the thousands and thousands of diverse living constructions, and the modifications of similar apparatus to serve diverse ends."

In 1846 Huxley was appointed naturalist to the expedition which was sent to the East under Captain Owen Stanley in the *Rattlesnake* and good use indeed he made of his opportunities. It is really wonderful, as Sir M. Foster remarks in his excellent obituary notice in the Royal Society's *Proceedings*, how he could have accomplished so much under such difficulties.

"Working," says Sir Michael Foster, "amid a host of difficulties, in want of room, in want of light, seeking to unravel the intricacies of minute structure with a microscope lashed to secure steadiness, cramped within a tiny cabin, jostled by the tumult of a crowded ship's life, with the scantiest supply of books of reference, with no one at hand of whom he could take counsel on the problems opening up before him, he gathered for himself during those four years a large mass of accurate, important and, in most cases, novel observations, and illustrated them with skilful, pertinent drawings."

The truth is that Huxley was one of those all-round men who would have succeeded in almost any walk in life. In literature his wit, his power of clear description and his admirable style would certainly have placed him in the front rank.

He was as ready with his pencil as with his pen. Every one who attended his lectures will remember how admirably they were illustrated by his blackboard sketches, and how the diagrams seemed to grow line by line almost of themselves. Drawing was, indeed, a joy to him, and when I have been sitting with him at Royal Commissions or on committees, he was constantly making comical sketches on scraps of paper or on blotting-books which, though admirable, never seemed to distract his attention from the subject on hand.

Again, he was certainly one of the most effective speakers of the day. Eloquence is a great gift, although I am not sure that the country might not be better governed and more wisely led if the House of Commons and the country were less swayed by it. There is no doubt, however, that, to its fortunate possessor, eloquence is of great value, and if circumstances had thrown Huxley into political life, no one can doubt that he would have taken high rank among our statesmen. Indeed, I believe his presence in the House of Commons would have been of inestimable value to the country. Mr. Hutton, of the *Spectator*—no mean judge—has told us that in his judgment "an abler and more accomplished debater was not to be found even in the House of Commons." His speeches had the same quality, the same luminous style of exposition, with which his printed books have made all readers in America and England familiar. Yet it had more than that. You could not listen to him without thinking more of the speaker than of his science, more of the solid, beautiful nature than of the intellectual gifts, more of his manly simplicity and sincerity than of all his knowledge and his long services. His Friday evening lectures at the Royal Institution rivalled those of Tyndall in their interest and brilliance, and were always keenly and justly popular. Yet, he has told us that at first he had almost every fault a speaker could have. After his first Royal Institution lecture he received an anonymous letter recommending him never to try again, as whatever else he might be fit for, it was certainly not for giving lectures. It is also said that after one of his first lectures, "On the relations of Animals and Plants," at a surburban Athenæum, a general desire was expressed to the Council that they would never invite that young man to lecture again. Quite late in life he told me, and John Bright said the same thing, that he was always nervous when he rose to speak, though it soon wore off when he warmed up to his subject.

No doubt easy listening on the part of the audience means hard working and thinking on the part of the lecturer, and, whether for the cultivated audience at the Royal Institution or for one to working men, he spared himself no pains to make his lectures interesting and instructive. There used to be an impression that Science was something up in the clouds, too remote from ordinary life, too abstruse and too difficult to be interesting; or else, as Dickens ridiculed it in Pickwick, too trivial to be worthy of the time of an intellectual being.

Huxley was one of the foremost of those who brought our people to realise that science is of vital importance in our life, that it is more fascinating than a fairy tale, more thrilling than a novel, and that any one who neglects to follow the triumphant march of discovery, so startling in its marvellous and unexpected surprises, so inspiring in its moral influence and its revelations of the beauties and wonders of the world in which we live and the universe of which we form an infinitesimal, but to ourselves at any rate, an all important part, is deliberately rejecting one of the greatest comforts and interests of life, one of the greatest gifts with which we have been endowed by Providence.

But there is a time for all things under the sun, and we cannot fully realise the profound interest and serious responsibilities of life unless we refresh the mind and allow the bow to unbend. Huxley was full of humour, which burst out on most unexpected occasions. I remember one instance during a paper on the habits of spiders. The female spider appears to be one of the most unsociable, truculent and bloodthirsty of her sex. Even under the influence of love, she does but temporarily suspend her general hatred of all living beings. The courtship varies in character in different species, and is excessively quaint and curious; but at the close the thirst for blood which has been temporarily overmastered by an even stronger passion, bursts out, with irresistible fury, she attacks her lover and, if he be not on the watch and does not succeed in making his escape, ends by destroying and sucking him dry. In moving a vote of thanks to the author, Huxley ended some interesting remarks by the observation that this closing scene was the most extraordinary form of marriage settlements of which he had ever heard.

He seemed also to draw out the wit of others. At the York "Jubilee" meeting of the British Association, he and I strolled down in the afternoon to the Minster. At the entrance we met Prof. H. J. Smith, who made a mock movement of surprise. Huxley said "you seem surprised to see me here." "Well," said Smith hesitatingly, "not exactly, but it would have been on one of the pinnacles, you know."

His letters were full of fun. Speaking of Siena in one of his letters, contained in Mr. Leonard Huxley's excellent Life of his father, he says: "The town is the quaintest place imaginable, built of narrow streets on several hills to start with, and then apparently stirred up with a poker to prevent monotony of effect."

And, again, writing from Florence:—

"We had a morning at the Uffizii the other day, and came back with minds enlarged and backs broken. To-morrow we contemplate attacking the Pitti, and doubt not the result will be similar. By the end of the week our minds will probably be so large, and the small of the back so small, that we should probably break if we stayed any longer, so think it prudent to be off to Venice."

By degrees public duties and honours accumulated on him more and more. He was Secretary, and afterwards President, of the Royal Society, President of the Geological and of the Ethnological Societies, Hunterian Professor from 1863 to 1870, a Trustee of the British Museum, Dean of the Royal College of Science, President of the British Association, Inspector of Fisheries, Member of Senate of the University of London, Member of no less than ten Royal Commissions, in addition to which he gave many lectures at the Royal Institution and elsewhere, besides, of course, all those which formed a part of his official duties.

In 1892 he was made a Member of the Privy Council, an unwonted but generally welcome recognition of the services which science renders to the community.

As already mentioned, he was elected a Fellow of the Royal Society in 1851. He received a Royal Medal in 1852, the Copley in 1888, and the Darwin Medal in 1894.

Apart from his professional and administrative duties, Huxley's work falls into three principal divisions—Science, Education and Metaphysics.

SCIENTIFIC WORK.

Huxley's early papers do not appear to have in all cases at first received the consideration they deserved. The only important one which was published before his return was the one "On the Anatomy and Affinities of the Family of the Medusæ."

After his return, however, there was a rapid succession of valuable Memoirs, the most important, probably, being those on Salpa and Pyrosoma, on Appendicularia and Doliolum and on the Morphology of the Cephalous Mollusca.

In recognition of the value of these Memoirs he was elected a Fellow of the Royal Society in 1851, and received a Royal Medal in 1852. Lord Rosse, in presenting it, said: "In these papers you have for the first time fully developed their (the Medusæ) structure, and laid the foundation of a rational theory for their classification." "In your second paper, 'On the Anatomy of Salpa and Pyrosoma' the phenomena, &c., have received the most ingenious and elaborate elucidation, and have given rise to a process of reasoning the results of which can scarcely yet be anticipated, but must bear, in a very important degree, upon some of the most abstruse points of what may be called transcendental physiology."

A very interesting result of his work on the Hydrozoa was the generalisation that the two layers in the bodies of Hydrozoa (Polyps and Sea Anemones), the Ectoderm and the Entoderm correspond with the two primary germ layers of the higher animals. Again, though he did not discover or first define protoplasm, he took no small share in making its importance known, and in bringing naturalists to recognise it as the physical basis of life, and in demonstrating the unity of animal and plant protoplasm.

Among other important memoirs may be mentioned those "On the Teeth and the Corpuscula Tactus," "On the Tegumentary Organs," "Review of the Cell Theory," "On Aphis," and many others.

His palæontological work, for which he has told us that at first "he did not care," began in 1855. That "On the Anatomy and Affinities of the Genus Pterygotus" is still a classic; in another, "On the Structure of the Shields of Pteraspis," and in one "On Cephalaspis" in 1858 he for the first time clearly established their vertebrate character; his work "On Devonian Fishes" in 1861 threw quite a new light on their affinities; and amongst other later papers may be mentioned that "On Hyperodapedon"; "On the Characters of the Pelvis," "On the Crayfish," and one botanical memoir, "On the Gentians," the outcome of one of his Swiss trips.

One of the most striking results of his palæontological work was the clear demonstration of the numerous and close affinities between Reptiles and Birds, the result of which is that they are regarded by many as forming together a separate group, the Sauropsida; while the Amphibia, long regarded as Reptiles, were separated from them and united with Fishes under the title of Ichthyopsida. At the same time he showed that the Mammalia were not derived from the Sauropsida, but formed two diverging lines springing from a common ancestor. And besides this great generalisation, says the Royal Society obituary notice, "the importance of which, both from a classificatory and from an evolutional point of view, needs no comment, there came out of the same researches numerous lesser contributions to the advancement of morphological knowledge, including, among others, an attempt, in many respects successful, at a classification of birds."

In conjunction with Tyndall, he communicated to the *Philosophical Transactions* a memoir on glaciers, and his interest in philosophical geography was also shown in his popular treatise on physiography.

But it would be impossible here to go through all his contributions to science. The Royal Society Catalogue enumerates more than a hundred, everyone of which, in the words of Prof. S. Parker, "contains some brilliant generalisation, some new and fruitful way of looking at the facts of science. The keenest morphological insight and inductive power are everywhere apparent; but the imagination is always kept well in hand, and there are none of those airy speculations—a liberal pound of theory to a bare ounce of fact—by which so many reputations have been made." Huxley never allowed his study of detail to prevent him from taking a wide general view.

I now come to his special work on Man.

In the "Origin of Species," Darwin did not directly apply his views to the case of Man. No doubt he assumed that the considerations which applied to the rest of the animal kingdom must apply to Man also, and I should have thought must have been clear to every one, had not Wallace been in some respects, much to my surprise, of a different opinion. At any rate, it required some courage to state this boldly, and much skill and knowledge to state it clearly.

He put it in a manner which was most conclusive, and showed, in Virchow's words, "that in respect of substance and structure Man and the lower animals are one. The fundamental correspondence of human organisation with that of animals is at present universally accepted."

This, I think, is too sweeping a proposition. It may be true for Germany, but it certainly is not true here. Many of our countrymen and countrywomen not only do not accept, they do not even understand, Darwin's theory. They seem to suppose him to have held that Man was descended from one of the living Apes. This, of course, is not so. Man is not descended from a Gorilla or an Orang-utang, but, Man, the Gorilla, the Orang-utang and other Anthropoid Apes are all descended from some far away ancestor.

"A Pliocene Homo skeleton," Huxley said, "might analogically be expected to differ no more from that of modern men than the *Œningen canis* from modern Canes, or Pliocene horses from modern horses. If so, he would most undoubtedly be a man—genus Homo—even if you made him a distinct species. For my part, I should by no means be astonished to find the genus Homo represented in the Miocene, say, the Neanderthal man, with rather smaller brain capacity, longer arms, and more movable great toe, but at most specifically different."

In his work "On Man's Place in Nature," while referring to the other higher Quadrumana, Huxley dwelt principally on the chimpanzee and the gorilla, because, he said, "It is quite certain that the ape, which most nearly approaches man in the totality of its organisation, is either the chimpanzee or the gorilla."

This is no doubt the case at present; but the gibbons (Hylobates), while differing more in size, and modified in adaptation to their more skilful power of climbing, must also be considered, and, to judge from Prof. Dubois' remarkable discovery in Java of Pithecanthropus, which half the authorities have regarded as a small man, and half as a large gibbon, it is rather down to Hylobates than either the chimpanzee or the gorilla that we shall have to trace the point where the line of our far-away ancestors will meet that of any existing genus of monkeys.

Huxley emphasised the fact that monkeys differ from one another in bodily structure as much or more than they do from man.

We have Haeckel's authority for the statement that, "after Darwin had, in 1859, reconstructed this most important biological theory, and by his epoch-making theory of natural selection placed it on an entirely new foundation, Huxley was the first who extended it to man; and in 1863, in his celebrated three lectures on 'Man's Place in Nature,' admirably worked out its most important developments."

The work was so well and carefully done that it stood the test of time, and writing many years afterwards Huxley was able to say, and to say truly, that

"I was looking through 'Man's Place in Nature' the other day; I do not think there is a word I need delete, nor anything I need add except in confirmation and extension of the doctrine there laid down. That is great good fortune for a book thirty years old, and one that a very shrewd friend of mine implored me not to publish, as it would certainly ruin all my prospects" ("Life of Prof. Huxley," p. 344).

He has told us elsewhere ("Collected Essays," vii. p. xi.) that "it has achieved the fate which is the Euthanasia of a scientific work, of being inclosed among the rubble of the foundations of knowledge and forgotten." He has, however, himself saved it from the tomb, and built it into the walls of the temple of science, and it will still well repay the attention of the student.

For a poor man—I mean poor in money, as Huxley was all

his life—to publish such a book at that time was a bold step. But the prophecy with which he concluded the work is coming true.

"After passion and prejudice have died away," he said, "the same result will attend the teachings of the naturalist respecting that great Alps and Andes of the living world—Man. Our reverence for the nobility of manhood will not be lessened by the knowledge that man is, in substance and in structure, one with the brutes; for he alone possesses the marvellous endowments of intelligible and rational speech, whereby, in the secular period of his existence, he has slowly accumulated and organised the experience which is almost wholly lost with the cessation of every individual life in other animals; so that now he stands raised upon it as on a mountain top—far above the level of his humble fellows, and transfigured from his grosser nature by reflecting here and there a ray from the infinite source of truth" ("Collected Essays," vii. p. 155).

Another important research connected with the work of our Society was his investigation of the structure of the vertebrate skull. Owen had propounded a theory and worked it out most ingeniously that the skull was a complicated elaboration of the anterior part of the backbone; that it was gradually developed from a preconceived idea or archetype; that it was possible to make out a certain number of vertebræ, and even the separate parts of which they were composed.

Huxley maintained that the archetypal theory was erroneous; and that instead of being a modification of the anterior part of the primitive representative of the backbone, the skull is rather an independent growth around and in front of it. Subsequent investigations have strengthened this view, which was now generally accepted. This lecture marked an epoch in vertebrate morphology, and the views he enunciated still hold the field.

One of the most interesting parts of Huxley's work, and one specially connected with our Society, was his study of the ethnology of the British Isles. It has also an important practical and political application, because the absurd idea that ethnologically the inhabitants of our islands form three nations—the English, Scotch and Irish—has exercised a malignant effect on some of our statesmen, and is still not without influence on our politics. One of the strongest arguments put forward in favour of Home Rule used to be that the Irish were a "nation." In 1887 I attacked this view in some letters to the *Times*, subsequently published by Quaritch. Nothing is more certain than that there was not a Scot in Scotland till the seventh century; that the east of our island from John o' Groat's House to Kent is Teutonic; that the most important ethnological line, so far as there is one at all, is not the boundary between England and Scotland, but the north and south watershed which separates the East and West. In Ireland, again, the population is far from homogeneous. Huxley strongly supported the position I had taken up. "We have," he said, "as good evidence as can possibly be obtained on such subjects that the same elements have entered into the composition of the population in England, Scotland and Ireland; and that the ethnic differences between the three lie simply in the general and local proportions of these elements in each region. . . . The population of Cornwall and Devon has as much claim to the title of Celtic as that of Tipperary. . . . Undoubtedly there are four geographical regions, England, Scotland, Wales and Ireland, and the people who live in them call themselves and are called by others the English, Scotch, Welsh and Irish nations. It is also true that the inhabitants of the Isle of Man call themselves Manxmen, and are just as proud of their nationality as any other 'nationalities.'

. . . .

"But if we mean no more than this by 'nationality,' the term has no practical significance" ("The Races of the Brit. Isles," pp. 44, 45).

Surely it would be very desirable, especially when political arguments are based on the term, that we should come to some understanding as to what is meant by the word 'nation.' The English, Scotch and Irish live under one Flag, one Queen, and one Parliament. If they are not one nation, what are they? What term are we to use, and some term is obviously required, to express and combine all three. For my part I submit that the correct terminology is to speak of Celtic race or Teutonic race, of the Irish people or the Scotch people; but that the people of England, Scotland and Ireland, aye, and of the Colonies also, constitute one great nation.

As regards the races which have combined to form the nation, Huxley's view was that in Roman times the population of Britain comprised people of two types, the one fair, the other dark. The dark people resembled the Aquitani and the Iberians; the fair people were like the Belgic Gauls ("Essays," V. vii. p. 254). And he adds that "the only constituent stocks of that population, now, or at any other period about which we have evidence, are the dark whites, whom I have proposed to call "Melanochroi" and the fair whites or "Xanthochroi."

He concludes (1) "That the Melanochroi and the Xanthochroi are two separate races in the biological sense of the word race; (2) that they have had the same general distribution as at present from the earliest times of which any record exists on the continent of Europe; (3) that the population of the British Islands is derived from them, and from them only.

It will, however, be observed that we have (1) a dark race and a fair race; (2) a large race and a small race; and (3) a round-headed race and a broad-headed race. But some of the fair race were large, some small; some have round heads, some long heads; some of the dark race again had long heads, some round ones. In fact, the question seems to me more complicated than Huxley supposed. The Mongoloid race extend now from China to Lapland; but in Huxley's opinion they never penetrated much further West, and never reached our islands. "I am unable," he says, "to discover any ground for believing that a Lapp element has ever entered into the population of these islands." It is true that we have not, so far as I know, anything which amounts to proof. We know, however, that all the other animals which are associated with the Lapps once inhabited Great Britain. Was man the only exception? I think not, more especially when we find, not only the animals of Lapland, but tools and weapons identical with those of the Lapps. I must not enlarge on this, and perhaps I may have an opportunity of laying my views on the subject more fully before the Society; but I may be allowed to indicate my own conclusion, namely, that the races to which Huxley refers are amongst the latest arrivals in our islands; that England was peopled long before its separation from the mainland, and that after the English Channel was formed, successive hordes of invaders made their way across the sea, but as they brought no women, or but few, with them, they exterminated the men, or reduced them to slavery, and married the women. Thus through their mothers our countrymen retain the strain of previous races, and hence perhaps we differ so much from the populations across the silver streak.

Summing up this side of Huxley's work, Sir M. Foster has truly said that, "whatever bit of life he touched in his search, protozoan, polyp, mollusc, crustacean, fish, reptile, beast and man—and there were few living things he did not touch—he shed light on it, and left his mark. There is not one, or hardly one, of the many things which he has written which may not be read again to-day with pleasure and with profit, and, not once or twice only in such a reading, it will be felt that the progress of science has given to words written long ago a strength and meaning even greater than that which they seemed to have when first they were read."

In 1870, Huxley became a member of the first London School Board, and though his health compelled him to resign early in 1872, it would be difficult to exaggerate the value of the service he rendered to London and, indeed, to the country generally.

The education and discipline which he recommended were:—

(1) Physical training and drill.

(2) Household work or domestic economy, especially for girls.

(3) The elementary laws of conduct.

(4) Intellectual training, reading, writing and arithmetic, elementary science, music and drawing.

He maintained that "no boy or girl should leave school without possessing a grasp of the general character of science, and without having been disciplined more or less in the methods of all sciences."

As regards the higher education, he was a strong advocate for science and modern languages, though without wishing to drop the classics.

Some years ago, for an article on higher education, I consulted a good many of the highest authorities on the number of hours per week which in their judgment should be given to the principal subjects. Huxley, amongst others, kindly gave me his views. He suggested 10 hours for ancient languages and literature, 10 for modern languages and literature, 8 for arithmetic and mathematics, 8 for science, 2 for geography, and 2 for religious instruction.

For my own part I am firmly convinced that the amount of

time devoted to classics has entirely failed in its object. The mind is like the body—it requires change. Mutton is excellent food; but mutton for breakfast, mutton for lunch, and mutton for dinner would soon make any one hate the sight of mutton, and so Latin grammar before breakfast, Latin grammar before lunch, and Latin grammar before dinner is enough to make almost any one hate the sight of a classical author. Moreover, the classics, though an important part, are not the whole of education, and a classical scholar, however profound, if he knows no science, is but a half-educated man after all.

In fact, Huxley was no opponent of a classical education in the proper sense of the term, but he did protest against it in the sense in which it is usually employed, namely, as an education from which science is excluded, or represented only by a few random lectures.

He considered that specialisation should not begin till sixteen or seventeen. At present we begin in our Public School system to specialise at the very beginning, and to devote an overwhelming time to Latin and Greek, which, after all, the boys are not taught to speak. Huxley advocated the system adopted by the founders of the University of London, and maintained to the present day that no one should be given a degree who did not show some acquaintance with science and with at least one modern language.

"As for the so-called 'conflict of studies,'" he exclaims, "one might as well inquire which of the terms of a Rule of Three sum one ought to know in order to get a trustworthy result. Practical life is such a sum, in which your duty multiplied into your capacity, and divided by your circumstances, gives you the fourth term in the proportion, which is your deserts, with great accuracy" ("Life of Prof. Huxley," p. 406).

"That man," he said, "I think, has had a liberal education, who has been so trained in youth that his body is the ready servant of his will, and does with ease and pleasure all the work that, as a mechanism, it is capable of; whose intellect is a clear, cold, logic engine, with all its parts of equal strength, and in smooth working order; ready, like a steam engine, to be turned to any kind of work, and spin the gossamers as well as forge the anchors of the mind; whose mind is stored with a knowledge of the great and fundamental truths of nature and the laws of her operations; one who, no stunted ascetic, is full of life and fire, but whose passions are trained to come to heel by a vigorous will, the servant of a tender conscience; who has learned to love all beauty, whether of nature or of art, to hate all vileness and to respect others as himself."

He was also strongly of opinion that colleges should be places of research as well as of teaching.

"The modern university looks forward, and is a factory of new knowledge; its professors have to be at the top of the wave of progress. Research and criticism must be the breath of their nostrils; laboratory work the main business of the scientific student; books his main helpers.

Education has been advocated for many good reasons: by statesmen because all have votes, by Chambers of Commerce because ignorance makes bad workmen, by the clergy because it makes bad men, and all these are excellent reasons; but they may all be summed up in Huxley's words that "the masses should be educated because they are men and women with unlimited capacities of being, doing and suffering, and that it is as true now as ever it was that the people perish for lack of knowledge."

Huxley once complained to Tyndall, in joke, that the clergy seemed to let him say anything he liked, "while they attack me for a word or a phrase." But it was not always so.

Tyndall and I went, in the spring of 1874, to Naples to see an eruption of Vesuvius. At one side the edge of the crater shelved very gradually to the abyss, and, being anxious to obtain the best possible view, I went a little over the ridge. In the autumn Tyndall delivered his celebrated address to the British Association at Belfast. This was much admired, much read, but also much criticised, and one of the papers had an article on Huxley and Tyndall, praising Huxley very much at Tyndall's expense, and ending with this delightful little bit of bathos:—"In conclusion, we do not know that we can better illustrate Prof. Tyndall's foolish recklessness, and the wise, practical character of Prof. Huxley, than by mentioning the simple fact that last spring, at the very moment when Prof. Tyndall foolishly entered the crater of Vesuvius during an eruption, Prof. Huxley, on the contrary, took a seat on the London School Board."

Tyndall, however, returned from Naples with fresh life and health, while the strain of the School Board told considerably on Huxley's health.

Huxley's attitude on the School Board with reference to Bible teaching came as a surprise to those who did not know him well. He supported Mr. W. H. Smith's motion in its favour, which indeed was voted for by all the members except six, three of whom were the Roman Catholics, who did not vote either way.

"I have been," he said, "seriously perplexed to know by what practical measures the religious feeling, which is the essential basis of conduct, was to be kept up, in the present utterly chaotic state of opinion on these matters, without the use of the Bible. Take the Bible as a whole; make the severest deductions which fair criticism can dictate for shortcomings and positive errors; eliminate, as a sensible lay-teacher would do if left to himself, all that it is not desirable for children to occupy themselves with; and there still remains in this old literature a vast residuum of moral beauty and grandeur. And then consider the great historical fact that for three centuries this book has been woven into the life of all that is best and noblest in English history; that it has become the national epic of Britain, and is as familiar to noble and simple, from John o' Groat's House to Land's End, as Dante and Tasso were once to Italians; that it is written in the noblest and purest English, and abounds in exquisite beauties of mere literary form; and, finally, that it forbids the veriest hind who never left his village to be ignorant of the existence of other countries and other civilisations, and of a great past, stretching back to the furthest limits of the oldest nations in the world. By the study of what other book could children be so much humanised and made to feel that each figure in that vast historical procession fills, like themselves, but a momentary space in the interval between two eternities, and earns the blessings or the curses of all time, according to its effort to do good and hate evil, even as they also are earning their payment for their work?"

(*To be continued*).

THE NUMBERS OF THE AMERICAN BISON.

IT is eleven years since Mr. Hornaday published his interesting account of the extermination of the American Bison—a work that was fully noticed in these columns at the time. The author then estimated the number of living survivors of the species at 1091, of which 256 were in captivity and 835 running wild in British North America, the Yellowstone Park, and a few other localities. Recently Mr. Mark Sullivan has attempted to make a fresh census of the species, the results of which form the subject of a long article published in the *Boston Evening Transcript* of October 10.

As the result of his inquiries, Mr. Sullivan estimates the number of bison living at the present time as approximately 1024, of which 684 are in captivity and 340 running wild or half wild. His investigations appear to have been conducted with great care; and in the case of the greater number of domesticated herds—whether American or foreign—the numbers are practically accurate. The number of those running wild in the neighbourhood of the Great Slave Lake has, however, been arrived at by a process of "averaging;" and the extent of the herd in the Yellowstone is to a large degree a matter of guess-work. Another element of uncertainty is introduced by the alleged existence of wild bison in the mountains of Colorado; for while a Government official vouches for their occurrence in considerable numbers, old bison-hunters are very sceptical whether there are any at all. Admitting that the report of their existence in this district may be true, the author allows 21 as their conjectural number. He adds that reports of wild bison in other parts of the United States are pure fabrications.

The largest herd of pure-bred domesticated bison living in the United States is one belonging to the heirs of the late Mr. C. Allard, which ranges over the Flathead Indian Reserve in Montana, and numbers 259 head. Next to this comes the herd of Mr. Jones Goodnight, in Armstrong County, Texas, with a total of 110 head. The number living in countries other than America is given at 100, of which 26 are in England, the Duke of Bedford's herd of 12 at Woburn Abbey being probably the largest in this country.

Whatever may be the real number of wild bison, it is evident from the figures given above that they have decreased very seriously since 1887, while those living in captivity exhibit, on

the other hand, a very marked increase in numbers. Although the bison in the Yellowstone are protected so far as possible from poachers, many of them fall victims to beasts of prey, and their rate of increase seems to be slow. Those in British territory are much harried by Indians, and are consequently decreasing daily in number.

It is accordingly to the domesticated and semi-domesticated herds that we have to look for the maintenance of the species. And with the example of the Lithuanian herd of European bison before us, coupled with the larger size of several of the American herds, and the facilities that exist for the introduction of fresh blood to counteract the ill-effects of inbreeding, there would seem, at first sight, to be a great probability that the American bison may survive for many generations.

It has, however, been brought to the notice of the writer of the article under consideration that, in the case of animals living under conditions other than those which properly belong to them, there is a great tendency for the proportion of males among the offspring to increase in an alarming degree at the expense of the females. And to such an extent does this abnormality prevail in some of the herds, that in Bronx Park, New York, every calf is put down as a bull as a matter of course. If this were universal, the fate of the species would evidently be soon sealed; but fortunately it is not so, and as the Allard herd wanders almost at will under what are practically the natural conditions of the species, there still appears (in spite of certain disabilities) hope that the final extinction of *Bos bison* is a remote contingency. R. L.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. A. J. Evans, Keeper of the Ashmolean Museum, will give three public lectures on "The Palace of Knossos: its Art Treasures and Clay Archives," explanatory of his recent work in Crete; the dates announced are November 22, November 29, December 6.

The trustees of the Craven Fellowships have made a grant of 200*l*. to assist Messrs. Grenfell and Hunt in their Egyptian researches.

On Thursday, November 15, the new degree of Doctor of Letters was conferred upon Mr. B. P. Grenfell, Mr. A. S. Hunt, and Mr. J. Rhys, Principal of Jesus College, and the degree of Doctor of Science upon Prof. A. E. H. Love and Mr. H. W. Lloyd Tanner.

Prof. Miers has been appointed a delegate for the inspection and examination of schools.

The report of the Delegacy for the Training of Teachers states that there were twenty-six students on the books of the College at the end of the academical year. Mr. Roscoe, having been appointed Lecturer on Education in the University of Birmingham, has been succeeded by Mr. A. W. Priestley as Master of Method at the Day Training College.

CAMBRIDGE.—The syndicate appointed to superintend the erection of the Hopkinson wing of the engineering laboratory report that the work has been successfully caried out at a cost of 5516*l*. Of this, Mrs. Hopkinson and her family contributed 5000*l*. Additional donations, amounting to 1700*l*., have been received for the furnishing and equipment of the building, which have thus been carried out without expense to the University. The classes, however, are still growing rapidly, and the accommodation is already insufficient. A further extension will soon have to be undertaken, and new workshops are much needed.

The Medical School Syndicate propose that the existing Museum of Surgery and Pathology, which has become so infected with dry-rot that it endangers the contiguous structures, shall be demolished, and that the new Humphry Museum shall be erected on its site at a cost of some 8000*l*. Over 1000*l*. has been specially contributed for this memorial to the late Sir George Humphry, and it is hoped that if the work is actually begun other donations to the building fund may be received.

THE *British Medical Journal* states that under the will of the late Dr. D. J. Leech, professor of materia medica and therapeutics in the Owens College, Manchester, that college will eventually benefit to the extent of 10,000*l*., which Dr. Leech bequeathed for the purpose of endowing a chair of materia medica and therapeutics. The bequest will take effect upon the demise of Mrs. Leech.

LORD ROSEBERY dealt with many Imperial questions in his Rectorial address at Glasgow University on Friday last, but none were of more importance than those concerned with the factors of industrial progress, and their educational relationships. The following extracts from the *Times* report of his speech are of particular interest to all who are engaged in the work of science or scientific education:—The United States Consul at Chemnitz has remarked that, "If an industry in Germany languishes, immediately a commission inquires into the causes and recommends remedial measures, among which usually is the advice to establish technical or industrial schools, devoted to the branch of business under consideration." In a word, they go to the root, to the principle, to the source. This is thoroughness, this is the scientific method applied to manufacture, and we see its success. The Americans, I gather, have hitherto applied themselves rather less to the principles than the applications of science. I do not pretend to say which are right. The Germans are alarmed at the development of American commerce, and we are alarmed at both. At any rate, both in Germany and the United States you see an expenditure and a systematic devotion to commercial, and technical, and scientific training. I know that much is done, too, in Great Britain. But I doubt if even that is carried out in the same methodical way; nor is there anything like the same lavish, though well-considered, expenditure. It always seems to me as if in Germany nothing, and in Britain everything, is left to chance.

For the practical purposes of the present day, said Lord Rosebery at Glasgow, a University which starts in the twentieth century has a great superiority over a University founded in the fifteenth, more especially when it is launched with keen intelligence of direction and ample funds, as is the new University of Birmingham. These practical Universities are the Universities of the future; for the average man, who has to work for his livelihood, cannot superadd the learning of the dead to the educational requirements of his life and his profession. There will always be Universities, or, at any rate, colleges, for the scholar, the teacher, and the divine; but year by year the ancient Universities will have to adapt themselves more and more to modern exigencies. There was a time, long years ago, when the spheres of action and of learning were separate and distinct, when laymen dealt hard blows and left letters to the priesthood. That was to some extent the case when our oldest Universities were founded. But the separation daily narrows, if it has not already disappeared. It has been said that the true University of our days is a collection of books. What if a future philosopher shall say that the best University is a workshop? And yet the latter definition bids fair to be the sounder of the two. The training of our schools and colleges must daily become more and more the training for action, for practical purpose. Are there not thousands of lads to-day plodding away, or supposed to be plodding away, at the ancient classics who will never make anything of those classics, and who, at the first possible moment, will cast them into space, never to reopen them? Think of the wasted time that that implies; not all wasted, perhaps, for something may have been gained in power of application, but entirely wasted so far as available knowledge is concerned. And if you consider, as you will have to consider in the stress of competition, that the time and energy of her citizens is part of the capital of the commonwealth, all those wasted years represent a dead loss to the Empire. If, then, these recent events and the present conditions of the world induce thinkers and leaders in this country to test our strength and methods for the great struggle before us, they must reckon the training of man. On that, under Providence, depends the future, and the immediate future, of the race; and what is Empire but the predominance of race?

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, November 1.—Prof. S. H. Vines, F.R.S., President, in the chair.—Mr. J. E. Harting exhibited and made remarks upon the following birds which had been recently forwarded to him for examination:—(1) A hybrid between blackcock and red grouse, shot at Brechin, N.B., September 14. (2) A glossy ibis, killed at Saltash, Devon, October 4. (3) A little owl, obtained at Dunmow, Essex, October 22. Mr. F. D. Godman concurred in identifying the game-bird as a hybrid

between the species named, and considered such hybrids of rare occurrence, while examples of a cross between blackcock and pheasant were not nearly so uncommon. Mr. Howard Saunders regarded the little owl (*Carine noctua*) as having little if any claim to be considered a British bird; its occasional appearance in England being due to the fact that a good many had been turned out from time to time in different counties.—Mr. George Massee exhibited a series of coloured drawings and an extensive collection of fungi.—Dr. Charles Chilton, M.A., F.L.S., read a paper on the terrestrial isopods of New Zealand.—M. J. E S. Moore read a paper on the character and origin of the "park-lands" in Central Africa. These park-lands in the Tanganyika district have quite the appearance of having been formed by the hand of man, but are really natural growths, due to the fact that light surface-soil has been laid down over what appear to have been lake-deposits. Any given line of country will show large plantations, with quite a home-like look, separated by grass-lands; and, as Tanganyika is approached, they dwindle in size till they consist of a few shrubs, overshadowed by giant euphorbias, cactus-like in appearance. Then come stretches of grass, dotted with euphorbias, and, last of all, the salt steppes by the lake, which is now held to have had at one time an outlet to the sea. Mr. Moore's explanation is that at first only the euphorbias would grow on the salt steppes; but as these sprang up they afforded a shade and shelter to self-sown shrubs, each of which, as it established a footing, contributed to the natural planting of the area by the distribution of its seeds, till this process reached its highest development in the large plantations where the shrubs overtopped the euphorbias to which they owed their growth.

Geological Society, November 7.—J. J. H. Teall, F.R.S., President, in the chair.—Additional notes on the drifts of the Baltic coast of Germany, by Prof. T. G. Bonney, F.R.S., and the Rev. E. Hill. The authors, prior to revisiting Rügen, examined sections of the drift to the west of Warnemünde, with a view of comparing it with that of the Cromer coast. The authors give reasons to show that neither solution of the chalk, nor ice-thrust, nor folding, nor even faulting, can satisfactorily explain the peculiar relations of the drift and chalk in Rügen; and they can find no better explanation than that offered in their previous paper.—On certain altered rocks from near Bastogne and their relations to others in the district, by Dr. Catherine A. Raisin. Prof. Renard, from the petrographical study of specimens, and Prof. Gosselet, after description of the district and its stratigraphy, have attributed the changes in these rocks to mechanical disturbances. Dumont had previously described many examples, and inclined to the view of contact-alteration, which was favoured by Von Lasaulx's discovery of a granite in the Hohe Venn, and M. Dupont's identification of chiastolite from Libramont. The present paper treats especially of the garnetiferous and hornblendic rocks, giving the full petrographical and field-details of a few examples. It points out that the effects of pressure are evident over the whole district, while mineral modifications resembling the results of slight contact-action are found in certain areas. In a few cases these modifications are more marked, and sometimes increase as we approach veins composed of quartz, felspar and mica, such as might be connected with a concealed granite. The peculiar garnetiferous and hornblendic rocks, although occurring within the zone of alteration, are extremely limited, often forming patches or bands a few feet across. They differ, as described in the paper, from ordinary contact-altered rocks. The evidence, in the authoress's opinion, is in favour of Prof. Bonney's suggestion that they are due to some form of hot-spring action.

Entomological Society, November 7.—Mr. G. H. Verrall, President, in the chair.—Mr. G. S. Saunders exhibited specimens, from Devonshire, of *Pieris rapae* and *Plusia gamma*, caught by the proboscis in flowers of *Araujia albens*, Don., a climbling plant of the natural order *Asclepiadaceae*; and explained the nature of the mechanism by which the insects were entrapped by the flowers. He also showed specimens of the "bedeguar" gall formed apparently on the "hips," or fruit, of *Rosa canina*. Mr. Gahan remarked that the capture of insects by the plant named had recently been investigated in France by MM. Marchand and Bonjour, whose account appeared in the *Bulletin* de la Soc. des Sciences Nat. de l'Ouest de la France, for 1899. These authors concluded that insects were captured only by immature flowers, the anther-wings, in the cleft between which the proboscis of the insect is caught, being at that time stiff and resistant; but when the flowers are ripe the anther-wings become less rigid and do not offer sufficient resistance to the withdrawal of the proboscis, which carries with it the pollinia ready to be transferred to the stigma of the next flower visited by the insect.—Mr. W. J. Kaye exhibited *Hydrocampa stagnalis*, var., with examples of the typical form for comparison; the variety differed in having the basal line nearly obsolete, the sub-median double line much strengthened internally and reduced externally, and the cross band connecting the sub-median and post-median bands almost entirely obliterated.—Mr. F. Merrifield exhibited a variety of *Argynnis dia* taken with a few examples of the ordinary form at Ilanz in the Vorder Rhein valley early in September last, when what was, he believed, a third brood of this species, was abundant; the variety was much blackened on the basal half of all the wings.—Canon Fowler exhibited a specimen of *Orochares angustatus*, Erichs., a Staphylinid beetle new to the British list, taken at Leverstock Green, Herts, by Mr. Albert Piffard.—The Rev. F. D. Morice mentioned, as a fact of some interest, that in a nest of *Formica sanguinea* at Weybridge, in which he found males and workers of that species, he found also males and females as well as workers of the slave-ant *Formica fusca*, an experience somewhat different to that of Huber and Darwin, who stated that workers only of the slave species were found in the nests of *sanguinea*.—The Secretary read "Some notes on variations of *Zeritis thysbe*, Linn.," communicated by Mr. H. L. L. Feltham, and exhibited one female and two male specimens of one of the rare forms referred to in the paper.

Mathematical Society, Nov. 8.—Lord Kelvin, G.C.V.O., President, in the chair.—Reports from the Treasurer and Secretaries were read and received. The ballot was taken and the gentlemen whose names appeared in NATURE for October 18 were declared to have been duly elected to serve on the Council for the session 1900–1901. Lord Kelvin, on leaving the chair, thanked the Society for having elected him to the office, and regretted that the distance (400 miles) of his home from town had caused him to be so rarely able to take the chair. He then cordially welcomed his successor, Dr. Hobson, and expressed his pleasure in having him for his successor. The new President thanked the members for electing him, and then called upon Lord Kelvin to deliver his address "On the transmission of force through a solid." The address was a very interesting one, and on the motion of Dr. Glaisher, seconded by Dr. Larmor and backed by the acclamation of the members present, Lord Kelvin consented to put his remarks into a shape fitted for publication in the Society's *Proceedings*.—Dr. Glaisher then communicated two papers: (i) A general congruence theorem relating to the Bernoullian function; (ii) On the residues of Bernoullian functions for a prime modulus, including as special cases the residues of the Eulerian numbers and the I-numbers.—Mr. Tucker next communicated some notes on Isoscelians, and gave a few properties of two in-triangles similar to the pedal triangle. These triangles have their sides perpendicular to the antiparallels of the primitive triangle.—The President communicated the remaining papers by simply reading their titles. In a simple group of an odd composite order every system of conjugate operators or subgroups includes more than fifty, Dr. G. A. Miller.—Prime functions on a Riemann surface, Prof. A. C. Dixon.—On Green's function for a circular disc, H. S. Carslaw.—On the real points of inflection of a curve, A. B. Basset.—On quantitative substitutional analysis, A. Young.—On a class of plane curves, J. H. Grace.—(i) On group characteristics, and (ii) On some properties of groups of odd order, Prof. W. Burnside.—(i) Conformal space transformations, and (ii) Dynamical and other applications of algebra of bilinear forms, T. J. Bromwich.

Mineralogical Society, November 13.—Prof. A. H. Church, F.R.S., President, in the chair.—Mr. G. F. Herbert Smith described an improved form of his three-circle goniometer, in which the use of an autocollimating telescope obviates the disadvantage of the original instrument that measurements could only be made through 93°.—Mr. Harold Hilton gave a simple proof of the rationality of the anharmonic ratio of four faces of a zone.—Mr. R. H. Solly, in continuation of the investigation of sulpharsenites of lead from the Binnenthal, described the crystallographic characters of rathite.

MANCHESTER.

Literary and Philosophical Society, October 30.—Prof. Horace Lamb, F.R.S., President, in the chair.—A paper on the solubility of certain lead glasses or fritts used in the preparation

of pottery glazes, by William Jackson and Edmond M. Rich, was read. The paper described experiments carried out to determine what factors, apart from chemical composition, affect the amount of lead oxide yielded to dilute hydrochloric acid by lead fritts as used by potters. It was found that the solubility is increased in a very marked manner by increase of fineness, so that it appears that if details are given of the solubility of fritts they should be accompanied by particulars of its degree of fineness. The solubility of the same fritt reduced to different degrees of fineness varied from 1 to 15 per cent. of the material used. It was found also that after the action of the acid has proceeded for a short time it appears that the whole of the soluble lead has been extracted. This, however, was due, not to the absolute insolubility of the remainder, but to the formation of an insoluble layer on the surfaces exposed to the action of acid which protects the particles from further action. By removing this layer by chemical or physical means it was found possible to extract more lead oxide from the fritt, and by continually removing this insoluble layer it was possible to extract continually more lead oxide, until practically the whole of the lead oxide passed into solution.—A paper on the phloem of *Lepidophloios* and *Lepidodendron* was read by Prof. F. E. Weiss. The author had examined sections of these two nearly allied fossil plants in which the tissues have been exceptionally well preserved. The examination of these specimens led him to the conclusion that the phloem region is not occupied by large secretory sacs, and that the tissue is not partially disorganised during the life of the plant, as has been suggested, but that it consists of cells not fundamentally different from those composing the phloem of living lycopods. In those stems, however, in which secondary thickening is found to have taken place, an active division of some of the phloem cells can be observed. The author discussed the possible reasons for the usual destruction of the phloem elements, and considered that it must take place previous to mineralisation, but after the death of the plant. He attributed the more ready destruction of the phloem cells to the peculiar nature of the cell walls, which he thought were probably composed—as in the case of the nearly allied lycopods—of amyloid, a semihydrate of cellulose. This substance is more easily acted upon by water than cellulose, and consequently the phloem would be more liable to rapid decay than the rest of the tissues.

November 13.—Prof. Horace Lamb, F.R.S., President, in the chair.—Prof. Reynolds mentioned a curious phenomenon observed at sunset during the summer, in the form of a narrow beam of light proceeding vertically from the sun and persisting for about half an hour after sunset. A similar appearance was seen by Mr. Thorp when crossing the Mediterranean in the early summer.—Dr. Lees called attention to a useful expression for calculating the circumference of an ellipse to a close degree of approximation, more simple than those ordinarily given in engineers' text-books.—Mr. Thorp described a method by which he had succeeded in silvering his diffraction films, and he referred to a device by which he expects to obtain similar films from concave surfaces.—Prof. Dixon discussed the reversal of lines of the spectrum of an explosion wave observed by Profs. Dewar and Liveing, and gave an alternative explanation to that offered by them. He also discussed Mendeléeff's theory as to the nature of the action which takes place when hydrogen and oxygen or other pairs of gases combine, and suggested an alternative view of the nature of the reaction.

EDINBURGH.

Royal Society, November 5.—Sir Arthur Mitchell, Vice-President, in the Chair.—As usual at the first meeting of the session, the chairman gave a short review of the work of the preceding session. In particular, attention was drawn to the bequest to the Society made by the late Prof. Piazzi Smythe; to the representation which the Society had made to the Geological Survey Committee as to the advisability of completing the survey of Scotland on the six-inch scale; and to the Scottish Antarctic Expedition now being organised by Mr. W. S. Bruce.—A paper was read by Drs. O. Noel Paton, J. C. Dunlop and Elsie Inglis on dietary studies of the poorer classes in Edinburgh. The diets of fifteen families, including ninety-five individuals belonging to the labouring classes, were studied by the method employed by Atwater in America. It was found that the average diet of the thrifty poor contained 108 grms. of proteid and 3275 large calories of energy per man per diem; but among the thriftless and ignorant very defective diets were observed. Such a deficient diet cost, for an average family of father, mother and four or five children, about 15*s*. 6*d*. per week, which leaves out of a labourer's wage of 20*s*. to 22*s*. a sum too small for the other necessaries of life and nothing for recreation.—In a note on the relations amongst the thermo- and electro-magnetic effects, Dr. W. Peddie showed how the Hall, the Nernst, the Ettingshausen and the Leduc effects may be represented in mutual relation, so that when, say, the Leduc effect is known, the others may be predicted. For this purpose consideration is taken of the direction of the resultant heat flow induced in consequence of the changes of temperature gradient evidenced in the Thomson effect. The Leduc effect is known only in the case of bismuth, yet, in the case of other metals, the possible signs of the remaining effects can be deduced; and the actual signs are found to be included in these in all cases except those of cobalt and zinc.

Mathematical Society, Nov. 9.—Mr. R. F. Muirhead in the chair.—The following papers were read: Euclidian proof of Pascal's theorem, by Mr. R. F. Davis.—Note on the expression for the area of a triangle, by Mr. C. Tweedie.—Proof of a theorem in co-ordinate geometry, by Mr. J. Jack (communicated by Mr. A. Milne).—The following were elected office-bearers for the current session: President, J. W. Butters; Vice-President, Geo. Duthie; Hon. Secretary, D. C. McIntosh; Hon. Treasurer, James Archibald.

PARIS.

Academy of Sciences, November 12.—M. Maurice Lévy in the chair.—On the next appearance of the Leonids, and their aërostatic observation, by M. J. Janssen. In order to prevent the interference of clouds with the observations of the Leonids, arrangements had been made for a balloon ascent on each of the three nights, November 13–14, 14–15, and 15–16, during which Leonids may be expected.—On the conditions affecting chemical activity under the action of silent electrical discharges, by M. Berthelot. The effects of silent electrical discharges ("effluve") and of atmospheric electricity are compared, the production of oxides of nitrogen, ozone and nitric acid being possible in this way without actual lightning. Some of the effects produced in Deville's hot and cold tube experiments, and ascribed by him to dissociation, are also ascribed by the author to similar electrical effects.—On the order of formation of the elements of the central cylinder in the root and stem, by M. Gaston Bonnier. The central cylinder presents the sam general structure in both root and stem, the constitution and the order of development of the tissues being the same in both cases, except as regards the position of the ligneous poles. The paper is illustrated by six diagrams showing sections of *Thalictrum silvaticum*, *Chenopodium polyspermum*, *Ricinus communis*, *Pulmonaria officinalis* and *Ranunculus acris*.—The Perpetual Secretary announced to the Academy the death of M. l'Abbé Armand David, Correspondent for the Section of Geography and Navigation.—On surfaces which possess a non-linear series of rational curves, by M. S. Kantor.—On the series analogous to Lagrange's series, by M. A. Bougaïev.—Superficial lines appearing in the sawing of metals, by M. Ch. Frémont. Six photographs are given of sections of different shapes cut by sawing. A series of lines, differing from the saw markings, are produced, which vary with the shape of the piece cut, the systems of lines being parallel to the edges cut by the saw. They differ from Lüder's lines.—On the experiments of Prof. Rowland relating to the magnetic effect of "electrical convection," by M. V. Crémieu. In previous communications the author has described experiments which led him to the conclusion that the so-called "electrical convection" produced no magnetic effect. Further experiments are now described, corresponding exactly to those of Rowland and of Himstedt, in which a charged disc rotates round a magnetised needle. In the first experiment no deviation of the needle was observed, although the effect should have been from 12 to 175 mm. In other experiments a deviation was obtained, but it is shown that these deviations are not due to the magnetic effect of the electrical convection, since they can be suppressed by the intervention of a metallic plate. The whole work tends to show that, contrary to the experiments of Rowland, electrical convection produces no magnetic effect.—On the splitting-up by alkalis of acetylenic ketones, by MM. Ch. Moureu and R. Delange. Ketones of the type $R-C\equiv C-CO.R'$ are split up by heating with alkalis. An acid and a ketone would, in general, appear to be produced simultaneously, thus benzoylphenylacetylene, $C_6H_5.C{:}C.CO.C_6H_5$, gives benzoic acid and acetophenone.

Acetylphenylacetylene behaves in an exceptional manner, giving phenylacetylene and acetic acid.—On the constitution of camphoric acid and the migrations which occur within its molecules, by M. G. Blanc.—On the evolution of terpene derivatives in the geranium, by M. Eug. Charabot. Acidity diminishes as the plant grows, and the amount of ester increases, possibly at the expense of the geraniol. The ketonic compounds occur chiefly at the time when the plant possesses the maximum respiratory activity.—On the presence of invertine or sucrase in grapes, by M. V. Martinand.—The old course of the Aar, near Meiringen (Switzerland), by M. Maurice Luglon.—On the regeneration of confined air by means of sodium peroxide, by MM. Desgrez and Balthazard. A reclamation of priority against H. G. F. Jaubert.

NEW SOUTH WALES.

Linnean Society, September 26.—The Hon. James Norton, President, in the chair.—Phosphorescent fungi in Australia, by D. McAlpine. Phosphorescent fungi are generally natives of warm climates, and the largest number of Agarics possessing this property, for any locality, has been met with in Australia. Out of twenty-one species known altogether, fifteen occur in Australia, while five of them are confined to the Island Continent. *Pleurotus candescens*, F.v.M., is very common in the neighbourhood of Melbourne during April and May, and was specially studied in connection with the phenomenon of phosphorescence or luminosity. Luminosity was practically confined to the gills, which were found to be decidedly acid. The light probably proceeded from excreted luminous metabolic products known as phosphorescents.—On a new genus and two new species of Australian *Coccidae*, by E. Ernest Green. A species of *Rhizococcus* from *Acacia decurrens* at Mittagong, N.S.W., and one of *Antecerococcus* (gen. nov.) from *Pittosporum eugenioides*, at Bathurst, N.S.W., are described.—Observations on the tertiary flora of Australia, with special reference to Ettingshausen's theory of the tertiary cosmopolitan flora, Part ii., by Henry Deane. The aspect of the subject particularly considered in this paper is the venation of leaves and its untrustworthiness in the determination of botanical affinities. Plants cannot be classified by their leaves, as their form and venation do not in any way correspond to the acknowledged botanical divisions. It is found that the same types occur in widely different orders and different types in the same genus. As to variability of types in the same genus, examples from the genera *Quercus* and *Eucalyptus* were given; and illustrations of closely similar and even undistinguishable leaves of distinct genera and orders were mentioned.—Notes on the botany of the interior of New South Wales, Part i., by R. H. Cambage. This first instalment is descriptive of the characteristics, distribution and relation to geological formation, of the more conspicuous members of the flora, such as the Eucalypts, Acacias, &c., noticeable between Bourke and Cobar, a distance of about 100 miles.—A fish disease from George's River, by R. Greig Smith. Under the proposed name of *Vibrio bresmiae* an organism is described which was isolated from the carcass of a fish found dying under suspicious circumstances in George's River. The organism is pathogenic to fish, producing death in about two days. It is non-phosphorescent, but is otherwise closely allied to this group of vibrions.—Australian land planarians: descriptions of new species, and notes on collecting and preserving, No. ii., by Thos. Steel. Three new species of *Geoplana* from Western Australia are described, and the occurrence of a new variety of *G. quinquelineata*, F. and H., is noted. These are of interest as being the first land planarians recorded from this part of Australia. The same new variety of *G. quinquelineata* is also recorded from South Australia, and a description of it is given. Another *Geoplana* found in the vicinity of Sydney is described as new.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 22.

ROYAL SOCIETY, at 4.30.—Further Note on the Spectrum of Silicium: Sir Norman Lockyer, K.C.B., F.R.S.—On Solar Changes of Temperature and Variations in Rainfall in the Region Surrounding the Indian Ocean: Sir Norman Lockyer, K.C.B., F.R.S., and Dr. W. J. S. Lockyer.—On the Restoration of Co-ordinated Movements after Nerve Crossing with Interchange of Function of the Cerebral Cortical Centres: Dr. R. Kennedy.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Telegraphs and Telephones at the Paris Exhibition, 1900: John Gavey.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—On the Berbers of Algeria, and their Connections with Prehistoric Egypt: D. Randall-MacIver and A. Wilkin.

FRIDAY, NOVEMBER 23.

PHYSICAL SOCIETY, at 5.—An Automatic Wheatstone's Bridge: W. C. D. Whetham.—The Anomalous Dispersion of Carbon: Prof. R. W. Wood.—The Liquefaction of Hydrogen: Dr. M. W. Travers.—On the Refraction of Sound by Wind: Dr. E. H. Barton.

SATURDAY, NOVEMBER 24.

ESSEX FIELD CLUB (Museum of Natural History, Stratford), at 7.—On the Variations in the Marine Animals on Coast of Essex during the last Ten or Twelve Years: Dr. H. C. Sorby, F.R.S.—Notes on the Eocene Fauna and Flora of Walton-on-Naze: J. P. Johnson.—British Wild Flowers Photographed from Nature: J. C. Shenstone.

MONDAY, NOVEMBER 26.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Expedition to Lake Tanganyika and the Country to the North: J. E. S. Moore.

SOCIETY OF ARTS, at 8.—Electric Oscillations and Electric Waves: Prof J. A. Fleming, F.R.S.

INSTITUTE OF ACTUARIES.—Inaugural Address by the President, C. D Higham.

TUESDAY, NOVEMBER 27.

ANTHROPOLOGICAL INSTITUTE, at 8.30.—On Stone Implements from Tasmania: J. Paxton Moir.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Paper to be further discussed*: The Metropolitan Terminus of the Great Central Railway: G. A. Hobson and E. Wragge.—*Paper to be read and discussed, time permitting*: Machinery for the Manufacture of Smokeless Powder: Oscar Guttmann.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Analytical Portraiture: Francis Galton, F.R.S.

WEDNESDAY, NOVEMBER 28.

SOCIETY OF ARTS, at 8.—Malaria and Mosquitoes: Major Ronald Ross.

THURSDAY, NOVEMBER 29.

GOLDSMITHS' INSTITUTE CHEMICAL SOCIETY, at 8.30.—The Profession of an Industrial Chemist: Dr. J. Lewkowitsch.

CONTENTS.

THURSDAY, NOVEMBER 29, 1900.

THREE BOOKS ON BIRDS.

The Birds of Ireland; an Account of the Distribution, Migration and Habits of Birds as Observed in Ireland, with all Additions to the Irish List. By R. J. Ussher and R. Warren. Pp. xxxii + 419. Illustrated. (London: Gurney and Jackson, 1900.)

The Story of the Birds. By C. Dixon. Pp. xiv + 304. (London: George Allen, 1900.)

Among the Birds. By Florence Anna Fulcher. Pp. iii + 253. (London: S.P.C.K, 1900.)

IN a few months half a century will have elapsed since the publication of the third and concluding volume of Thompson's "Birds of Ireland," and, with the exception of a smaller volume written on more popular lines, and the valuable "List of Irish Birds" (two editions of which have appeared), by the late Mr. A. G. More, of Dublin, no other complete treatise on the same subject has hitherto been issued. With the great advances in our information on this special subject, and the improvements in our method of treating natural history in general, to say nothing of the changes which have occurred in the Irish avifauna itself during that long interval, it will be evident that there is abundant room for an authentic and standard work of the nature of the one before us. And no one could have been found better fitted to undertake this important and laborious task than Mr. R. J. Ussher, who has written the bulk of the present volume, and who has devoted the greater part of his life to the study of the history and habits of his well-beloved Irish birds. As regards the contributions of Mr. R. Warren, whose name appears on the title-page as joint-author, we are told in the preface that the portions of the work actually from his own pen are restricted to the accounts of half-a-dozen species. Mr. Ussher is, however, careful to acknowledge his indebtedness to his friend and coadjutor for a number of observations on the habits and distribution of birds. And he likewise declares his obligations to the late Mr. More, and also to Mr. R. M. Barrington, who has contributed much information with regard to bird-migration, drawn from the observations taken at the lighthouse stations.

Mr. Ussher appears, indeed, to have carried out his task in a thoroughly satisfactory and conscientious manner; and has succeeded not only in producing an accurate and trustworthy treatise on Irish birds, but likewise a readable and interesting book. With the many illustrated works extant at the present day on British birds, it would have been merely a useless expense to have repeated figures of the species found in Ireland; and a wise discretion has, we venture to think, been exercised in limiting the illustrations (which can scarcely be surpassed for excellence) to photographs of the nests of birds and of the breeding haunts of some of the maritime species. An exquisite coloured plate of six distinct colour-phases of Irish peregrine falcon eggs forms an appropriate frontispiece.

A feature of the work is the special attention bestowed on the local distribution of birds within the area treated of; this being elaborated in a series of tables which alone serve to indicate the enormous amount of labour bestowed by Mr. Ussher on his subject. In formulating these tables, he owns himself greatly indebted to correspondents from all parts of the country, who have filled up schedules sent to them for the purpose of recording their observations. So far as our recollection serves us, similar tables have not been issued with any work on the birds of Britain generally; and, in view of the present trend of natural history studies, the importance of those drawn by Mr. Ussher can scarcely be over-estimated.

In regard to classification and nomenclature, Mr. Ussher follows Mr. Saunders, in his "Manual of British Birds," and since, in our opinion, uniformity is of more importance than anything else in classification, we think he has been well advised in so doing. With the exception of the red grouse, he apparently regards no species of bird as peculiar to the British Islands; neither are any local Irish races admitted. In regard to the British marsh-tit, which Dr. Sharpe considers entitled to rank as a species apart from the continental form, under the name of *Parus dresseri*, Mr. Ussher admits no such distinction. Curiously enough, however, the subspecific title *Parus palustris dresseri* occurs in the index, but on turning to the page (31) quoted, only the name *P. palustris* is to be found. It may also be noted that on p. 230 the author refers to the generally lighter colour of Irish red grouse as compared with their relatives in Great Britain; and if this be a constant point of distinction, it would justify, in the opinion of many naturalists, the separation of the former as a local race.

It may be noticed that in the preceding paragraph we have employed the word "apparently" in regard to the absence of peculiar British species and races. We have done so because we have not been at the pains to look at the heading under which each particular bird is described, and there is no table of contents to the book in which it could be seen at a glance whether or no the above statement is absolutely correct. The omission of such a table is, we think, a decided disadvantage to the book. Its presence would likewise have told us the number of species of birds regarded by Mr. Ussher as entitled to be called Irish; but, as he does not number his species, this also can only be ascertained by going through the book page by page.

Not that this question of the number of species is one of much importance one way or the other, for, as the author tells us, it is always difficult to draw lines in cases of this nature. On the whole, however, we think that a wise discretion has been exercised in this particular instance, the species whose claims to admission rest on the slenderest foundations being treated by themselves. Apart from its fossilised bones, the only historic evidence in modern times for regarding the great auk as an Irish bird is furnished by the example captured near Waterford Harbour in 1834; and consequently the account of this species might with advantage have been considerably curtailed, as almost more than enough has been written about it in other works.

Occupying the most western position of the islands of the British group, and enjoying a singularly equable and mild climate, Ireland naturally cannot lay claim to the possession of nearly so many species of birds as are found within the limits of Great Britain. This deficiency

in species is, however, in some degree compensated by the great numerical abundance of certain of these in individuals, many of the coast cliffs, with their adjacent islands, being frequented during the breeding season by vast flocks of gannets, gulls, auks, puffins, guillemots, petrels, &c.

In regard to the eggs of guillemots, it may be mentioned that Mr. Ussher makes two interesting observations. In the first place, he says that the beautiful varieties of colouring, which are so characteristic of the eggs of this species, "must help each bird to distinguish her egg from others lying near, until they all become stained and soiled." In another passage he observes that the eggs "get completely covered in filth as incubation proceeds, and I have seen many cemented thereby to the rock. This may account for the exaggerated statement that the bird has the power of gluing them to the rock to prevent them from falling off."

In connection with the uniform climate of Ireland, to which reference has already been made, it may be observed that climatic conditions can scarcely explain all the features in the distribution of birds; this being remarkably exemplified by the circumstances that while the red-breasted merganser has an extensive breeding range in Ireland, yet that elsewhere in the British Islands its breeding is restricted to Scotland.

In regard to "station," Ireland, as most of our readers are doubtless well aware, possesses a variety which renders it peculiarly adapted to an abundant development of bird life. These variations are excellently well displayed in a map, in which the uncultivated areas are tinted brown. *Primâ facie*, it might have been thought that all the moors and bogs of Ireland were equally well suited to maintain a large bird population. But this, according to Mr. Ussher, is by no means the case, most of the western moors being comparatively destitute of life. The reason for this we should like to see explained.

Many birds now rare in England are comparatively common in Ireland, among them being the raven and the chough. Of the former Mr. Ussher writes that "in the west it still breeds undisturbed on the Arran Islands, High Island, and the Twelve Pins of Connemara, while the cliffs of Mayo and of Achil Island are among its chief strongholds." We presume there is no danger to the bird in the mention of these localities, as otherwise the author would not have done so, since he states, on page 374, that the disclosure of the nesting haunts of the red-throated diver led to its extermination as a breeding Irish species.

While Ireland has lost certain members of its original fauna, such as the great auk, the crane and the capercaillie, it has gained others by apparently natural causes. Among these latter are the missel-thrush and the magpie, both of which have now thoroughly well established themselves. Sportsmen will be pleased to learn that woodcock are yearly becoming more numerous during the summer in Irish coverts. And although it was feared some years ago that the quail was about to forsake the country for ever, its reappearance in some numbers during 1892–93 affords hope that it may some day be reestablished. All efforts to introduce the blackcock and the ptarmigan have, however, resulted in signal failure, and Mr. Ussher refuses to admit certain evidence derived from cavern bones as to their former existence in the island.

In conclusion, we cannot but repeat our sense of the high value and importance of Mr. Ussher's work, which must long remain the standard authority on the subject of which it treats. Errors and misprints are few and far between, and most of them have been detected and corrected by the author. The book is thoroughly well turned out, and should have a place on the bookshelves, not only of every British ornithologist, but of every sportsman who visits Ireland.

Of a very different character from the above is the book standing second on our list, which appeals only to the amateur ornithologist. Mr. Dixon and his publishers seem, indeed, to be under the impression that the British public has an unlimited appetite for popular bird-books, and to supply this an endless stream of works is poured from this author's pen. In the present volume Mr. Dixon takes a new departure, and tries to interest his readers in the anatomy and general structure of birds, as well as in their geographical distribution, both past and present.

Although a compilation, in which the author confesses himself much indebted to Prof. Newton's "Dictionary of Birds," the account of the palæontology and osteology is, on the whole, satisfactory. Perhaps, however, the statement on page 3, that reptiles are more nearly related to birds than to any other animals, might advantageously be modified in view of recent investigations into the structure of the anomodonts; and it is not true that all dinosaurs are gigantic. Exception may also be taken to the statement on page 13, that the tropical types of birds whose remains occur in the European tertiaries are necessarily of southern origin, the available evidence, for what it is worth, pointing to a precisely opposite conclusion. Neither do we think the idea mooted on page 105, "that some scheme of latitudinal division will yet be proved to be the correct one" for the division of the globe into zoo-geographical distribution is at all likely to find acceptation among those best qualified to deal with this subject.

In the osteological section, no indication is given that the so-called tibia of the bird (p. 35) includes a portion of the tarsus, or that the remaining part of that element is fused with the compound bone incorrectly called metatarsus.

After treating of their palæontology, structure, and distribution, Mr. Dixon takes into consideration their general habits and physiology, including flight, social instincts, food, mimicry and protective coloration, nuptial display, song, and nidification. All these subjects are treated in a manner calculated to attract the interest of the general reader. But there are some ugly sentences; as, for instance, the following on p. 29:—

"The first cervical vertebra is termed the atlas, because it bears the head, and which is articulated with it by a single occipital condyle."

And the work is not free from misprints, as witness (p. 115) *Merganettine* instead of *Merganettinae*. Nevertheless, the book, as a whole, is a creditable production; and it has the great merit of drawing attention to the fact that the scope of ornithology is not confined to the c lours and other external characters of birds.

Essentially popular and "gossipy" in its style, Miss Fulcher's "Among the Birds" is written by an enthusiastic bird-lover for other bird-lovers—whether young or old—who desire information on a fascinating subject without entering into zoological technicalities. As we learn from the preface, a number of the chapters have already appeared in various journals and magazines; and, in spite of the multitude of bird-books relating to the British Islands, they seem decidedly worthy of reproduction in permanent form. For the author has much of the fascination of style characteristic of "A Son of the Marshes," and writes mainly, if not entirely, from personal experiences of her feathered friends, her observations extending from the peaceful meadows and fields of Middlesex and Hertfordshire to the rugged moors and sea-cliffs of Scotland and the Farne Islands. Indeed, if the author has a fault, it is in a somewhat overweening confidence in her own opinions and theories, this being especially noticeable in the chapter on migration. And in this connection it may be mentioned that there are other English ornithologists besides Mr. C. Dixon who have written on the last-mentioned subject.

Personally we are of opinion that the author is at her best when describing birds in their actual haunts, the chapters on migration, nests, song and the "ministry of birds" being far less satisfactory than those dealing with the avifauna of particular stations. The chapters which strike us as being the most interesting are those entitled "The Tern Nursery on the Noxes," "Birds on the Wide Opens," "Guillemots on the Pinnacles," "Puffins" and "Birds of a Sea Marsh." In the second of these we have been particularly attracted by the description of the oyster-catcher. "Its form," writes the author, "is attractively odd and quaint as it rests heavily on its long and delicate pink legs. But the feature which distinguishes it from all British birds is the beak—the great staff of coral on which the bird seems to rest, when it stands with head bent, as a kangaroo rests on its tail—the great load of coral which seems to weight the bird's head so that it bows at every step it walks, and which it holds out like a herald's trumpet as it flies: two great mandibles of coral, thick and long, twice as long as the bird's head, and almost twice as thick as its long and slender legs. Why it requires such an implement is not quite clear." This, which is by no means a solitary instance, is distinctly original, and originality is a consummation much to be desired in natural history writings.

With the ways of the poacher the author displays considerable familiarity; and her statement of the manner in which illicitly killed grouse are preserved in Ireland till the 12th of August will probably be a revelation to many of our readers. She is perhaps unnecessarily severe on those who enjoy a dish of roast larks or a plover's egg; and, we believe, she decidedly over-estimates the fear of any serious diminution in the number of either lapwings or larks in this country. But all will be with the author in her endeavour to promote increased protection for birds in such cases as it may be demonstrated to be necessary.

In spite of the competition to which allusion has already been made, it may be hoped that lovers of birds will find a place in their bookcase for the present attractive little volume. R. L.

CHRONICA MATHEMATICA.

A Brief History of Mathematics. An authorised translation of Dr. Karl Fink's "Geschichte der Elementar-Mathematik." By W. W. Beman and D. E. Smith Pp. xii + 334. (London: Kegan Paul, Trench Trübner and Co., Ltd., 1900.)

THANKS, in great measure, to the unwearied industry and acumen of Dr. Moritz Cantor, it is now comparatively easy to construct a synopsis of mathematical history down to the beginning of the nineteenth century. It is true that success depends upon much more than a mere knack of précis-writing: the task requires judgment, discrimination and a certain kind of sympathy; still, the labour of such a work is greatly simplified now that the essential facts have been made accessible in Dr. Cantor's incomparable lectures. But when the historian loses the aid of this accomplished guide, and endeavours to carry on the tale down to our own time, he is at once met by serious difficulties, even if he confines himself to a strictly limited field. Most of the writers of popular histories of mathematics break down hopelessly when they reach the nineteenth century; they are hampered by the limitations of their own knowledge, and a consciousness of the difficulty of writing so as to be understood by the audience to whom they address themselves.

Prof. Fink, with rare and admirable courage, has disdained to shirk the problem, and has made a conscientious effort to trace the development of his subject down to the present day. The range of his work is limited to "elementary mathematics," that is to say, arithmetic, elementary geometry and algebra, and trigonometry; this has, of course, lightened his task considerably. But he has kept in view the connection of these subjects with those far-reaching theories which have grown out of them during the century now drawing to its close; and this has led him to give an outline of the course of modern research in such things as the theory of equations, function-theory, projective geometry, and non-Euclidian geometry. Moreover, he has not neglected to draw attention to the various tendencies of contemporary schools, and the directions of current investigation.

To do all this in such brief compass has involved severe limitations. Prof. Fink writes for the mathematical student, not for the dilettante, and assumes that his reader is acquainted with the ordinary technical terms of the science. Legendary biographies and items of irrelevant gossip are rigorously excluded; the author has faith enough in the intrinsic interest of his subject to refrain from larding it with scraps of tittle-tattle. The style, too, is concise almost to a fault; the translation, at any rate (and, we should imagine, the original work as well), is not distinguished either by grace or lucidity. But the substantial merits of the book, its well-considered plan its general trustworthiness, and its stimulating character, deserve cordial recognition.

In a work of this kind mistakes in detail are practically unavoidable. No one man possesses such a thorough knowledge of mathematics as to protect him from occasional error when he tries to make a survey of the whole field, or of any considerable part of it. For the correction of such inevitable errors the author must depend

upon the help of those who have paid special attention to particular lines of research; and it is with the intention of doing a service of this kind that the remarks which now follow have been made.

On p. 137 "the form $x \equiv a$ (mod. b), identical with $\frac{x}{b}=y+a$" should be corrected, at the end, by printing $x=by+a$. On p. 142 Reuschle's tables of 1856 are mentioned, but not his "Tafeln complexer Primzahlen" (Berlin, 1875). By an extraordinary oversight, it is said, on p. 207, that "we can construct a regular polygon of n sides only when $n-1=2^{2^p}$ (p an arbitrary integer)," although a correct statement (so far as it goes [1]) is given, pp. 161–2. On page 162, again, it is apparently said that Baltzer was the first to notice that 2^n+1 is not always prime when n is a power of 2; as a matter of fact, Euler proved that $2^{32}+1$ is divisible by 641 (*cf.* Smith's "Report on the Theory of Numbers," Art. 61).

On page 259, after explaining von Staudt's interpretation of "imaginary points" as double elements of involution-relations (which is not strictly correct: the involution itself, *plus* a distinguishing "sense," is the imaginary point), the author says, "This suggestion of von Staudt's, however, did not become generally fruitful, and it was reserved for later works to make it more widely known by the extension of the originally narrow conception." Besides being rather disparaging in tone, this is likely to convey a wrong impression. It is true that Kötter and others, in trying to extend von Staudt's theory to curves of higher orders, have been led to introduce involutions of a more general kind than his; but this does not affect his definition of an imaginary point, which is perfectly general and complete. The imaginary points in which a curve of any order is met by any line must admit (theoretically) of representation by involutions in von Staudt's sense: just as an equation with ordinary complex coefficients has a set of ordinary complex roots. The equation may be, from some points of view, insoluble or irreducible, and we may find it convenient to keep all its roots together; it is this which corresponds to the case of these "higher" involutions.

There are some obscurities which may be due to the author or translators or both. Thus, p. 250, "Möbius started with the assumption that every point in the plane of a triangle ABC may be regarded as the centre of gravity of the triangle:" (this is partially cleared up by the context). On p. 205, line 4, the sentence beginning "The semiparameter" is unintelligible, and is probably a mistranslation. Page 147, "the theory of binary forms has been transferred by Clebsch to that of ternary forms (in particular for equations in line co-ordinates)" is a very inadequate account of Clebsch's "Uebertragungsprincip," and will hardly convey any definite idea to the average reader.

Two obvious slips in translation may perhaps be mentioned. On p. 270, through not noticing an idiomatic inversion, the subject of a sentence has been treated as the predicate, and *vice versâ*: read "this point is offered by the eleventh axiom." On p. 203, for "and also with the normals" read "that is to say, with the normals:" *also* has been confused with *auch*, or rather with our "also." Finally, by the omission of an "s," Plücker has been made to say that "he (Monge) introduced the equation of the straight line into analytical geometry."

At the end of the book there are short biographical notices of a number of mathematicians: the list has been recast by the translators. Whether it is worth the space it occupies (26 pp.) is rather doubtful. Many entries are either trivial, or anticipated in the previous part of the book. Some of the notes are misleading, to say the least. Cauchy is said to have "contributed" to the theory of residues, the fact being that he invented it. All that is said of Eisenstein is that "he was one of the earliest workers in the field of invariants and covariants"; this is true in a sense, but his fame rests principally on his arithmetical memoirs, and his researches on doubly infinite products and elliptic unctions. Sophie Germain "wrote on elastic surfaces." Legendre "discovered the law of quadratic reciprocity," an erroneous statement which may be corrected by p. 138 of the book itself. And what is the use of such entries as "Donatello, 1386—1468. Italian sculptor"? It would be an improvement to cut down this list to the really important names, and to give indications of such trustworthy biographies, or other sources of information, as may be available. G. B. M.

[1] The necessary and sufficient condition that a regular polygon of n sides may admit of Euclidean construction with rule and compass is that the "totient" of n is a power of 2; in other words, $n=2^m pqr \ldots$, where m is zero or any natural number, and $p, q, r \ldots$ are *different* odd primes, *each* of the form 2^k+1. The values of n below 100 are excluding 2) 3, 4, 5, 6, 8, 10, 12, 15, 16, 17, 20, 24, 30, 32, 34, 40, 48, 51, 60, 64, 68, 80, 85, 96.

THE SCIENCE OF COLONISATION.

New Lands: their Resources and Prospective Advantages. By H. R. Mill, D.Sc., LL.D. Pp. xi + 280. (London: Charles Griffin and Co., Ltd., 1900.)

THE present is a very appropriate time for the publication of this book. Public attention is occupied with Imperialism and colonial development, so that a trustworthy statement of the resources and conditions of life in the countries of the temperate zone, where there is still an opening for the energies of English-speaking people, should be of real service. The colonies and countries described from this point of view are Canada, Newfoundland, United States, Mexico, Temperate Brazil, and Chile, Argentina, the Falkland Islands, Australia and Tasmania, New Zealand and South Africa. To intending settlers and capitalists desiring to know the prospects of success in these countries the book will be invaluable; for it brings together in a convenient and concise form all the essential particulars available in official reports and other authoritative works.

This is what the practical man wants, and he will probably not concern himself seriously with the chapter in which the development of new lands is considered in its scientific aspects, yet to our minds this chapter is the most valuable in the book, and every statesman and colonial official anxious that the progress of his country shall be steady and permanent should be familiar with the principles it contains. It is an instructive statement of the factors which ought to be considered in connection with the development of every land, but are often neglected.

Take, for instance, the subject of geographical boundaries. It is the British habit not to give any serious attention to this subject until forced to do so by a dispute with a neighbouring nation. As Dr. Mill remarks:

"Such a muddle as that respecting the boundary of Alaska, and futile suggestions like those which were made for the boundaries of British Guiana, before the final settlement, could never have been made if the statesmen who were responsible had consulted geographers, and had acted on their advice."

Related to this is the subject of topographical surveys. It ought to be a political axiom that a Government should know its country; but we are all aware how frequently this duty is neglected, and the war in South Africa has brought the deficiency into unpleasant prominence. Even the "man in the street" is now in a state of mind to agree that

"If the survey of British South Africa had been begun years ago, or even as late as 1880, and pushed forward with an ample supply of trained surveyors, the war of 1899-1900 within its borders would have been simpler, safer and immensely cheaper."

In addition to topographical surveys, there should be geological surveys, hydrographic surveys, climatological surveys, biological surveys, and other official determinations of the features, fauna and flora of the country, with a view to possessing trustworthy information for future as well as present service. The fundamental value of a knowledge of rainfall in determining the value of colonisable countries is not often recognised, though so much depends upon it. How important an extensive system of rain measurement is in some new countries is shown by the fact that Australians in their calculations often convert inches of rain into numbers of sheep or even pounds of wool per acre. This and other similar cases justify Dr. Mill's remark that

"in almost every case it will be found that the crux of a new land is the water supply. Water, as rain or rivers, is indeed the very life-blood of the habitable world, and the phenomena of its circulation are often complicated, and require much study to elucidate."

It is unnecessary in these columns to give further instances of the dependence of the success of the colonist upon the scientific information available concerning his adopted country. The difficulty is to relieve practical politicians of the thought that knowledge for which there is no immediate use is useless; they have no sympathy with purely scientific work, therefore they are unwilling to encourage it. Let us hope that in the course of time our statesmen will receive an early training in scientific method and foresight, sufficient to enable them to consider colonisation as a study in anthropogeography instead of a haphazard system of settlement.

OUR BOOK SHELF.

The Child: a Study in the Evolution of Man. By A. F. Chamberlain, M.A., Ph.D. Pp. i—xii + 495. With Illustrations. The Contemporary Science Series. (London: Walter Scott, Ltd., 1900.)

This book is intended as a study of the child in the light of the literature of evolution; an attempt to record and, if possible, interpret some of the most interesting and important phenomena of human beginnings in the individual and in the race. Anthropology, as a science embracing many aspects of the human race, is concerned with inquiry as to the evolution of man, and applies fresh knowledge, gained by scientific methods, to the correlation of ascertained facts. The book refers more to the psychological aspect of human development than to the physiological causes of evolution; dealing in a philosophical spirit—not always by strictly scientific processes—with the several subjects dealt with, evidence is afforded by the collection of data and the opinions expressed by many writers rather than based upon the author's own observations and arguments.

In the opening chapter on "the helplessness of infancy" the results that follow from early weakness and the prolonged period of dependency are shown by numerous quotations, while explanation is afforded by reference to Mr. Fiske's view that this has led to the lengthened association of children with their parents and thus developed social habits. The comparative adolescence and longevity of man and animals is shown, and the dictum of Schleiermacher, "Being a child must not hinder becoming a man; becoming a man must not hinder being a child," suggests application to education.

The periods of childhood suggested as distinctive of stages in development are numerous, and definitions from Pythagorus downwards are given. Dr. Chamberlain says, "not only does the child seem to recapitulate physically and mentally the chief points of the race's history, but his own development is fairly teeming with epochs and periods, isolated spots sometimes, the interpretation of which is not yet at hand." The examples given are very interesting, but do not convince us that there is sufficient evidence of any standard by which normal psychological development can be judged. The successive manifestations of mental growth in children form a promising field in child-study; the account given of the linguistic periods in the advance towards speech forms one of the most interesting chapters in this book. Other chapters are explanatory of the relations of the child with the savage and criminal showing certain analogies, but do not afford much guidance in studying child-evolution or explain why the children are such as we find them to be.

The desire to explain the evolution of infancy has sometimes led the author wide of the teaching of scientific views, as when he says, p. 442, "The moment Nature decided that, with man, the struggle for existence was ultimately to be altruistic, rather than selfish, she was forced to make man weak in order to ensure his later strength in the right direction." Such teaching leads the student to neglect the facts of physiology and the effects of physical environment.

The book presents much of interest to the philosophical reader, and maintains the contention that the teaching of evolution and child-study should go hand in hand as mutually instructive.

The value of this volume would be increased by a table of contents; this want is accentuated by the brevity of the index. Eighteen illustrations afford useful explanations of types of manhood and the artistic productions of children.

Sieroterapia e Vaccinazioni preventive contro La Peste Bubonica. Dott Alessandro Lustig. Pp. vi + 150. (Torino: Rosenberg and Sellier, 1899.)

This book gives an account of the preparation of anti-plague serum by the author's method.

According to Prof. Lustig, a considerable degree of immunity against plague is obtained by inoculating animals with a nucleo-proteid contained in the bodies of the bacilli. A culture of plague bacilli grown on solid media is scraped off and dissolved in a 1 per cent. solution of caustic potash. After washing and passing through a Chamberland filter, the substance is used for inoculating horses.

After repeated inoculations the horses are bled, and the serum is used for treatment of plague patients.

Or a solution of the nucleo-proteid may be used as a prophylactic, as advocated by Prof. Lustig and Galeotti (*British Medical Journal*, February 10, 1900). The curative treatment was tried for a period at the Arthur Road Hospital, Bombay, but the results were not very

satisfactory. We have now however a paper before us, by Dr. A. Mayr, read at the Bombay Medical Union, April 21, 1900, dealing with more recent trials, in which there were 38·2 per cent. of recoveries in 403 patients treated, the recoveries of patients under ordinary treatment being 19·5 per cent.

Whether the nucleo-proteid be used as a prophylactic to inoculate persons or to immunise horses to prepare a curative serum, it is evident that the antitoxin given rise to in the person or the horse is an antitoxin against the poisonous nucleo-proteid; the stakes in the race for recovery are all placed on the nucleo-proteid.

But it is not improbable that the metabolic products formed by the plague microbe in the medium it grows on—be it the body or an artificial medium—require to be immunised against, and herein lies the distinction between Haffkine's prophylactic and Lustig's nucleo-proteid used as a prophylactic. Haffkine uses the bodies of the bacilli together with the broth they have grown in, for he considers the broth acted upon by their growth to be useful if not essential. This has been shown to be the case in experiments on animals by Dr. Balfour Stewart (*British Medical Journal*, March 3, 1900).

Lustig's nucleo-proteid prophylactic has some technical advantages in its preparation over Haffkine's, but for the reasons pointed out above it is not likely to be as efficacious. C. B. S.

A Monograph of the Erysiphaceae. By Ernest S. Salmon, F.L.S. "Memoirs" of the Torrey Botanical Club. Vol ix., Pp. 292. (New York: 1900).

THE Torrey Botanical Club has performed a valuable service to mycologists in the publication of this excellent monograph of the Erysiphaceæ, a group of parasitic fungi causing the diseases known as white mildew, powdery mildew, blight, *Mehlthau*, *blanc*, &c. In their conidial or "oidium" stage they are common throughout the summer on various host-plants, such as roses, hops, vines, peas, maples, and many wild plants, giving a mealy appearance to the part infected; while in the later summer or autumn the perfect ascigerous form is produced in the form of dark brown or black spots, consisting of peritheces containing ascospores, and usually provided with characteristic appendages.

The number of known species of this well differentiated group of fungi is not large; the author describes forty-nine, including a very few new ones, in addition to a number of well-marked varieties. These are arranged in six genera, Podosphæra, Sphærotheca, Uncinula, Microsphæra, Erysiphe, and Phyllactinia. Great confusion exists in the nomenclature of the European species, and the author corrects several prevalent errors. He regards the ascus as the result of a true sexual process, and does not support Dangeard's view that the fusion of the nuclei in the young ascus is of sexual signification.

The monograph is illustrated by nine plates, and is supplemented by a very copious bibliography, in which no less than 400 distinct works or papers are referred to, and a host-index of the plants attacked by these fungi. A. W. B.

An Old Man's Holidays. By The Amateur Angler. Pp. xii + 140. (London: Sampson Low, Marston and Co., 1900.)

"AN AMATEUR ANGLER" is an observer of nature as well as an enthusiastic Waltonian, the result being that these holiday sketches contain here and there an observation of interest to naturalists. Referring to the growing scarcity of kingfishers he says, "This is partly owing to the fact that they have the credit of being destructive enemies of young trout; the fact is, they do feed on little fishes, but not so much on trout as on minnows, dace, sticklebacks, miller's thumbs, and even leeches" The book contains several illustrations of rural scenes.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Buchner's Zymase.

THE most recently issued number of the *Proceedings* of the Royal Society (No. 438) contains a paper by Dr. McFadyen, Dr. Morris and Mr. Rowland on the subject of Buchner's zymase, which is held by many observers to be the alcohol-producing enzyme of yeast.

The authors describe a long series of experiments which they have carried out, partly on Buchner's lines, and partly by new methods of their own. They find, as Buchner and other investigators have done, that yeast will, under proper conditions, yield up an extract which can set up alcoholic fermentation in a solution of cane sugar. Many very interesting points have come out during the progress of their work, the explanation of which is not at present very obvious; their conclusion, however, seems to call for a very careful scrutiny of the operations, especially as it has been advanced by other writers also. They state at the end of their paper that their experiments cause them to doubt the existence of an enzyme, and lead them rather "in the direction of a theory which refers the phenomenon to the vital activity of the yeast-cell protoplasm" (p. 265).

In reviewing their experiments it is noticeable that, in their preparation, the yeast was mixed with a certain proportion of kieselguhr, and subjected in this condition to the enormous pressure of 200-300 atmospheres (p. 252). The liquid thus expressed was capable of filtration under pressure through a Chamberland or Berkefeld filter (p. 259) without losing its properties, though the process decreased its power. It was miscible with, or soluble in, a small quantity of water or solution of cane-sugar without being altogether destroyed, though too much of the solvent inhibited its action (p. 262). The experiments were conducted throughout in the presence of antiseptics, such as 1 per cent. of sodium arsenite, thymol, or toluol (p. 254).

It will be difficult for physiologists to accept a conception of a protoplasm which is not destroyed by such a pressure as was used, and which afterwards becomes to some extent soluble in water, or, at any rate, miscible with it, which can be filtered through a porcelain filter without destruction, and which can carry on an anabolic and subsequently a katabolic process (p. 265) in the presence of such antiseptics as were used.

The authors say in an earlier part of the paper (p. 253) that such a kieselguhr "sponge" as they obtained during the extraction of the yeast was capable of retaining almost entirely the globulins of eggs, and, to a large extent, albumin and serum proteids. It seems strange after this to find them holding the view that protoplasm itself was not retained by such a "sponge."

It is a little difficult to reconcile their concluding theory of a fluid protoplasm with their statement (p. 253) that the juice they obtained and used was in every case far removed in nature from the condition in which it existed when alive in the yeast cell, even if one were to admit that the *juice* was ever living at all. Is it possible, in their opinion, for the anabolic and katabolic activities of protoplasm to be manifested in such a juice as they describe in those words? Yet their final hypothesis is that the yeast juice exhibits the "vital activity of the yeast-cell protoplasm."

I venture to disagree with their conclusion. In my own experiments, which were published in the *Annals of Botany*, vol. xii (1898), p. 491, I found that an active preparation could be obtained by grinding the yeast with kieselguhr in such proportion that a perfectly dry impalpable powder resulted, and then extracting the latter with a solution of cane-sugar. It is hardly credible that protoplasm without the protection of cell-walls, can resist desiccation. The action of the extract in my experiments, as in theirs, was considerable in the presence of antiseptics which, in the proportions used, were inevitably and rapidly fatal to the life of protoplasm.

Cambridge, November 19. J. REYNOLDS GREEN.

Euclid i. 32 Corr.

MR. TUCKER is right (p. 58) in his conjecture that Clavius was not the first to publish these corollaries.

References:—P. Ramus (ob. 1572), "Scholar^m. Math^m. Libri unus et triginta. *A Lazaro Schonero recogniti et emendati*,"

p. 180. Francofurti, 1599; H. Billingsley, the first English translation of the "Elements of Euclid," Fol. 42. (London, 1570); N. Tartalea Brisciano, "Euclide," Fol. 32. (Venetia, 1565); J. Peletarius, "In Euclidis Elementa Geometrica Demonstrationum Libri sex." Prop. 32. *Appendix a Campano*, pp. 33, 34. (Lugduni, 1557).

It is much to be regretted that in this country so little importance is attached to the history of mathematics; otherwise, such mistakes as those mentioned by Mr. Tucker would not be repeated from one text book to another.

Galway, November 17. GEORGE J. ALLMAN.

Instruments of Precision at the Paris Exhibition.

IN your issue of November 15 (p. 61) is an account of "Instruments of Precision at the Paris Exhibition," in which it is stated that a catalogue of 250 pages has been prepared by the German Association of Mechanicians and Opticians. May I ask you to state in some future issue how that catalogue can be obtained, as I am anxious to get a copy of it?

E. T. WARNER.

H.M.S. *Britannia*, Dartmouth, November 21.

I AM much interested in the article in the number of NATURE for November 15, on optical and other instruments at the Paris Exhibition. Although I visited the exhibition, I did not see the exhibit, as I went too soon after the opening. I should much like to obtain the catalogue mentioned. Will you kindly tell me where I should be able to obtain one by writing for it?

H. DAVIDGE.

Seafield Park College, Crofton, Hants, November 17.

[For information as to the German Catalogue of Scientific Instruments, application should be made to Dr. Robert Drosten, Bureau de l'Exposition allemande des Instruments de Precision, Classe 15, Section 3, Exposition Universelle, Paris. If Dr. Drosten is not in Paris, letters will probably be forwarded. The secretary of the German Committee of Management is Prof. St. Lindeck, Reichsanstalt, Charlottenburg, Berlin, who no doubt would send a catalogue.—ED. NATURE.]

ON SOLAR CHANGES OF TEMPERATURE AND VARIATIONS IN RAINFALL IN THE REGION SURROUNDING THE INDIAN OCEAN.[1]

I.

THE fact that the abnormal behaviour of the widened lines in the spectra of sunspots since 1894 had been accompanied by irregularities in the rainfall of India suggested the study and correlation of various series of facts which might be expected to throw light upon the subject.

The conclusions already arrived at from bringing together the results of several investigations undertaken with this view may be stated as follows:—

(1) It has been found from a discussion of the chemical origin of lines most widened in sunspots at maxima and minima periods that there is a considerable rise above the mean temperature of the sun around the years of sunspot maximum and a considerable fall around the years of sunspot minimum.

(2) It has been found from the actual facts of rainfall in India (during the S.W. monsoon) and Mauritius, between the years 1877 and 1886,[2] as given by Blanford and Meldrum, that the effects of these solar changes are felt in India at sunspot maximum, and in Mauritius at sunspot minimum. Of these the greater is that produced in the Mauritius at sunspot minimum. The pulse at Mauritius at sunspot minimum is also felt in India, and gives rise generally to a secondary maximum in India.

India therefore has two pulses of rainfall, one near the maximum and the other near the minimum of the sunspot period.

(3) It has been found that the dates of the beginning of these two pulses on the Indian and Mauritius rainfall are related to the sudden remarkable changes in the behaviour of the widened lines.

(4) It has been found from a study of the Famine Commission reports that all the famines therein recorded which have devastated India during the last half century (we have not yet carried the investigation further back) have occurred in the intervals between these two pulses.

(5) It has been found from the investigation of the changes in (1) the widened lines, (2) the rainfall of India and (3) of the Mauritius during and after the last maximum in 1893 that important variations from those exhibited during and after the last maximum of 1883 occurred in all three.

It may be stated at the same time that the minimum of 1888–1889 resembled the preceding minimum of 1878–1879.

(6) It has been found from an investigation of the Nile curves between the years 1849 and 1878 that all the lowest Niles recorded have occurred between the same intervals.

(7) The relation of the intervals in question to the droughts of Australia and of Cape Colony, and to the variations in the rainfall of extra tropical regions generally has not yet been investigated. We have found, however, a general agreement between the intervals and the rainfall of Scotland (Buchan), and have traced both pulses in the rainfalls of Córdoba (Davis) and the Cape of Good Hope.

(8) We have had the opportunity of showing these results to the Meteorological Reporter to the Government of India and Director-General of Indian Observatories, John Eliot, Esq., C.I.E., F.R.S., who is now in England, and he allows us to state his opinion that they accord closely with all the known facts of the large abnormal features of the temperature, pressure and rainfall in India during the last twenty-five years, and hence that the inductions already arrived at will be of great service in forecasting future droughts in India.

Solar Physics Observatory, October 26.

ADDENDUM.

Since Meldrum and one of us called attention, in 1872 to a possible connection between sunspots and rainfall, there has been a large literature upon the subject which it is not necessary for us to analyse; it may be simply stated that, in spite of the cogent evidence advanced since, chiefly by Meldrum, and in later years by Mr. Hutchins,[1] it is not yet generally accepted that a case for the connection has been made out.

What has been looked for has been a change at maximum sunspots only; the idea being that there might be an effective change of solar temperature, either in excess or defect, at such times; and that there would be a gradual and continuous variation from maximum to maximum.

At the same time, it is possible that the pressure connection, first advanced by Chambers, is now accepted by meteorologists as a result of the recent work of Eliot.

The coincidence, during the last few years, of an abnormal state of the sun with abnormal rain in India, accompanied by the worst famine experienced during the century, suggested to us the desirability of reconsidering the question, especially as we have now some new factors at our disposal. These have been revealed by the study, now extending over twenty years, of the widened lines in sunspots, which suggested the view that two effects ought to be expected in a sunspot cycle instead of one.

[1] By Sir Norman Lockyer, K.C.B., F.R.S., and W. J. S. Lockyer, M.A. (Camb.), Ph.D. (Gött.). Paper read before the Royal Society on November 22.

[2] This period was selected because the Kensington observations of widened lines only began in 1879, and the collected rainfall of India has only been published to 1886.

[1] "Cycles of Drought and Good Seasons in South Africa, 1889."

The Widened Lines.

It will be gathered from previous communications to the Royal Society[1] that, on throwing the image of a sunspot on the slit of a spectroscope, it is found that the spectrum of a spot so examined indicates that the blackness of the spot is due, not only to general, but to selective absorption,[2] and that the lines widened by the selective absorption vary from time to time.

Since the year 1879, the *selective* absorption in spots has been observed for every spot that was large enough to be spectroscopically examined; the method adopted being as follows:—

The regions of the spectrum investigated lie between F—*b* and *b*—D, and an observation consists in observing the six most widened lines in each of these regions. These lines are then identified on the best solar spectrum maps available and their wave-lengths determined.

An examination of many years' records of these widened lines has shown that at some periods they are easily traceable to *known* elements, while at others their origins have not been discovered, so the latter have been classed as "unknown" lines. If we compare these two periods with the sunspot curve as constructed from the measurements of the mean spotted area for each year, it is found that when the spotted area is greatest the widened lines belong to the "unknown" class, while when the spotted area is least they belong to the "known" class.

The majority of the lines traced to some terrestrial origin belong to iron, but the lines of other elements, such as titanium, nickel, vanadium, scandium, manganese, chromium, cobalt, &c., are also represented in a less degree.

It is quite likely that some of the "unknown" lines are higher temperature (enhanced) lines of known chemical elements.

In our laboratories we have means of differentiating between three stages of temperature, namely, the temperature of the flame, the electric arc, and the electric spark of the highest tension. At the lowest temperature, that of the flame, we get a certain set of lines; a new set is seen as the temperature of the electric arc is reached. At the temperature of the high tension spark we again have many new lines, called enhanced lines, added, while many of the arc lines wane in intensity.

It is found that at sunspot minimum, when the "known" lines are most numerous, the lines are almost invariably those seen most prominent in the arc. Passing from the sunspot minimum towards the maximum the "unknown" lines gradually obtain the predominance. As said before, they may be possibly "enhanced lines"—that is, lines indicating the action of a much higher temperature on *known* substances.

Unfortunately the records of enhanced lines at South Kensington, having been obtained from photographs, are chiefly confined to a region of the spectrum not covered by the visual observations of widened lines in sunspot spectra.

We can only point to the evidence acquired in the case of one metal—iron, for which photographs of the enhanced lines in the green and yellow parts of the spectrum have been obtained.

This evidence quite justifies the above suggestion, for the enhanced lines of iron can be seen revealing themselves as the number of unknown lines increases.

We are, therefore, quite justified in assuming a very great increase of temperature at the sunspot maximum when the "unknown" lines appear alone.

The curves of the "known" and "unknown" lines have been obtained by determining for each quarter of a year the percentage number of known and unknown lines and plotting these percentages as ordinates and the time elements as abscissæ. Instead of using the mean curves for all the known elements involved, that for iron is employed, as it is a good representative of "known" elements, and has been best studied. When such curves have been drawn they cross each other at points where the percentage of unknown lines is increasing, and that of the iron or known lines are diminishing, or *vice versâ*.

We seem, therefore, to be brought into the presence of three well-marked stages of solar temperature.

When the curves of known and unknown lines cross each other, that is, when the number of known and unknown lines is about equal, we must assume a mean condition of solar temperature. When the unknown lines reach their maximum we have indicated to us a + pulse or condition of temperature. When the known lines reach their maximum we have a − pulse or condition of temperature.

The earliest discussion showed that, generally speaking, the unknown-lines curve varied directly, and the iron-lines curve varied inversely with the spot-area curve. The curves now obtained for the whole period of twenty years not only entirely endorse this conclusion, but enable more minute comparisons to be drawn.

The "widened line" curves are quite different from those furnished by the sun-spots. Ascents and descents are both equally sharp, changes are sudden, and the curves are relatively flat at top and bottom. The crossings are sharply marked.

During the period since 1879 three such crossings have occurred, indicating the presence of mean solar temperature conditions, in the years 1881, 1886-7,[1] and 1892. It was expected that another crossing with the known lines on the rise would have occurred in 1897, indicating thereby the arrival of another mean condition of solar temperature, but as yet no such crossing has taken place.

The following tabular statement shows the years of those crossings, together with the probable dates, in brackets, of the two previous crossings, as determined by the time of occurrence of the preceding sun-spot maximum.

Rise of	Years		
Unknown lines ...	(1869)	1881	1892
Known lines ...	(1876)	1886–7	?

Comparison of Solar and Terrestrial Weather.

It has long been known that a cycle of solar weather begins in about lat. 32° N. and S., and in a period of 11 years ends in about lat. 5° N. and S.

Just before one cycle ends another commences. The greatest amount of spotted surface occurs when the solar weather-changes produced in the cycle reach about lat. 16° N. and S.

It becomes, therefore, of the first importance to correlate the times of mean solar temperature, and of the + and − heat pulses, with the solar weather cycle, in order to arrive at the temperature-history of the sun during the period which now concerns us. This may be done as follows:—

Solar cycles				→				→		→
Lat. of spots	19°	16°	12°	9°	18°	17°	10°	7°	19°	18°
Heat condition	mean	+	mean	−	mean	+	mean	−	mean	+
Years	1869	1870–5	1876	1877–80	1881	1882–6	1886–7	1888–91	1891–2	1892–

[1] *Proc. Roy. Soc.*, vol. xl. p. 347, 1886; vol. xlii. p. 37, 1887; vol. xlvi. p. 385, 1889; vol. lvii. p. 199, 1894.

[2] *P.R.S.*, Lockyer, 1866, October 11.

[1] According to the observations the mean was reached in December 1886, or January 1887.

Connection of the Spots with Prominences.

In 1869, when a sun-spot maximum was approaching, the prominences were classified by one of us into *eruptive* and *nebulous;* the former showing many metallic lines, the latter the hydrogen and helium lines chiefly. This conclusion, which was published in 1870, was subsequently confirmed and adopted by Secchi, Zöllner, Spörer, Young and Respighi.

In the same year prominences on the sun's disc were also observed by one of us by means of the C and F lines.[1]

The eruptive prominences, unlike the nebulous ones, were not observed in all heliographic latitudes; but, according to the extended observations of Tacchini and Ricco, had their maxima in the same latitude as the spots. This is especially well shown by the diagrams illustrating the distribution of spots, faculæ, eruptions and protuberances which are given by Tacchini for 1881–1887 in the *Memoria della Soc. degli Spettroscopisti Italiani*, 1882–1888. These curves show in the most unmistakable manner that the spots, faculæ and eruptive or metallic prominences have their maximum frequency in the same solar latitudes while the nebulous or quiet prominences are more uniformly distributed, and even have maxima in zones where spots are rarely observed. This is corroborated by what Prof. Respighi many years ago stated:

"In correspondence with the maximum of spots, not only does the number of the large protuberances increase, but more than this—their distribution over the solar surface is radically modified."

In his observations, Prof. Young found that the H and K lines of calcium were reversed in the chromosphere as constantly as *h* or C, and the same lines "were also found to be regularly reversed upon the body of the sun itself, in the penumbra and immediate neighbourhood of every important spot."[2] This result was confirmed by the early (1881) attempts of one of us to photograph the spectra of the chromosphere and spots, and also by eclipse photographs. In the photographic spectrum, the H and K lines are by far the brightest of the chromospheric lines, and this fact has been utilised by Hale and Deslandres acting on a suggestion due to Janssen, for the purpose of photographing at one exposure the chromosphere and prominences, as well as the disc of the sun itself, in the light of the K line.

These photographs thus give us in K light the phenomena which one of us first observed by the lines C and F of hydrogen, and thereby present a record of the prominences across the whole disc of the sun as well as at the limb.

In such photographs near sunspot maximum, the concentration of the prominences in zones parallel to the equator is perfectly obvious at a glance. Eruptive or metallic prominences are thus seen to cover a much larger area than the spots, so that we have the maximum of solar activity indicated, not only by the increased absorption phenomena indicated by the greater number of the spots, but by the much greater radiation phenomena of the metallic prominences; and there seems little doubt that in the future the measure of the change in the amount of solar energy will be determined by the amount and locus of the prominence area.

Spots are, therefore, indications of excess of heat, and not of its defect, as was suggested when the term "screen" was used for them. We know now that the spots at maximum are really full of highly heated vapours produced by the prominences, which are most numerous when the solar atmosphere is most disturbed.

The Indian meteorologists have abundantly proved that the increased radiation from the sun on the upper air currents at maximum is accompanied by a lower temperature in the lower strata, and that with this disturbance of the normal temperature we must expect pressure changes. Chambers was the first to show that large spotted area was accompanied by low pressures over the land surface of India ("Abnormal Variations," p. 1).

Passing, then, from the consideration of individual spots to the zones of prominences, with which they are in all probability associated, it is of the highest interest to note the solar latitudes occupied when the crossings previously referred to took place, as we then learn the belts of prominences which are really effective in producing the increased radiation. The area of these is much larger, and therefore a considerable difference of radiation must be expected.

The greater disturbance of certain zones of solar latitude seems to be more influential in causing the + pulse than the amount of spotted area determined from spots in various latitudes.

It is all the more necessary to point this out because the insignificance of the area occupied by the spots has been used as an argument against any easily recognised connection between solar and terrestrial meteorological changes.[1]

Assuming two belts of prominences N. and S., 10° wide, with their centres over Lat. 16°, a sixth of the sun's visible hemisphere would be in a state of disturbance.

THE KITE WORK OF THE UNITED STATES WEATHER BUREAU.

EARLY in the year 1898, the Congress of the United States granted a sum of money, to be expended under the direction of the Chief of the Weather Bureau, for the establishment and maintenance of a series of stations at which observations of the upper free air were to be made by means of automatically recording mechanisms attached to kites. This work was to be undertaken primarily in the hope that daily simultaneous observations might be obtained at definite altitudes, thus permitting the construction of daily synchronous charts of pressure, temperature, and wind direction and velocity, which, when studied in connection with corresponding surface charts, would admit of some advance being made in the present system of weather forecasting, both in accuracy and in the duration of the periods forecasted for.

FIG. 1.—Kite with meteorograph in position.

Seventeen stations were established in the spring of

1 "So far as can be judged from the magnitude of the sun-spots, the cyclical variation of the magnitude of the sun's face free from spots is very small compared with the surface itself; and consequently, according to mathematic principle, the effect on the elements of meteorological observation for the whole earth ought also to be small" (Eliot, "Report on the Meteorology of India in 1877," p. 2).

the year 1898, mostly in the great river valleys and the upper portion of the region of the Great Lakes. The form of kite used was the Hargrave cellular (Fig. 1), with such modifications and improvements as trial and experiment dictated. The surface dimensions of the

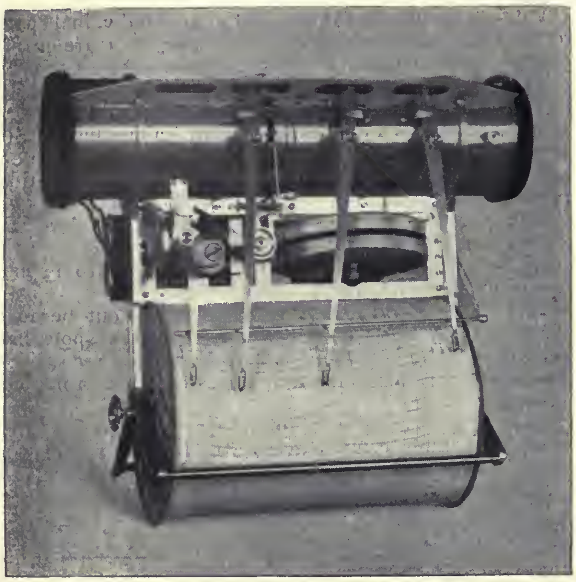

FIG. 2.—Kite meteorograph.

kites varied from 45 to 72 square feet. The kite line was carried on a large iron drum or reel, capable of resisting a crushing pressure of at least 1000 tons, and consisted of steel piano-wire ·028 inch in diameter, and weighing 2·15 pounds to the thousand feet, or 11·35 pounds to the mile. The tensile strength of this wire at the breaking-point was about 200 pounds.

With a kite flying at an elevation of from 5000 to 7000 feet, from 8000 to 10,000 feet of wire would be out, making a weight of from 90 to 115 pounds which must be sustained by the kite.

The meteorograph (Fig. 2), or automatic recording apparatus, was devised by Prof. C. F. Marvin, of the Weather Bureau. It weighs but a fraction over two pounds, is inclosed in an aluminium case, and, while quite complicated in construction, is remarkable for its compactness and lightness. The cylinders carrying the record sheets are actuated by clockwork, and four different meteorological conditions are recorded, viz., pressure, temperature, relative humidity and wind velocity (Fig. 3). The wind direction, of course, becomes apparent by observing the azimuth of the kite.

It soon became evident that there was no possibility of obtaining a daily synchronous chart. The principal difficulties were the very frequent absence of sufficient wind to sustain the kites, and inability to obtain ascensions in stormy weather. Taken as a whole, ascensions were possible during only 46 per cent. of the time from May to October, inclusive, the percentage varying from 75 at Dodge, Kansas, to 12 at Knoxville, Tennessee. The hours of the day at which ascensions could be made also varied greatly.

But however disappointing the results obtained may have been from the viewpoint of the weather forecaster, they were not so when considered from another. Much valuable data was obtained from the 1217 ascensions and 3835 observations, particularly regarding vertical temperature gradients, and it is believed that there has been a very material contribution made to our previous knowledge of this subject. Briefly summarised, the results of the observations were as follows:—

The mean rate of diminution of temperature with increase of altitude was found to be 5° F. for each 1000 feet, or only 0·4° less than the true adiabatic rate. The gradient was greatest up to 1000 feet, where it was 7·4° F.; from thence up to 5000 feet there was a steady decrease to 3·8° a thousand feet, the rate of decrease varying inversely with the altitude. Above 5000 feet there was a tendency toward a slight increase.

The mean gradients on the Atlantic coast were much smaller than those in the interior, the difference being mainly due to the lower morning values of the former, those of the afternoon differing but slightly. Inversions of temperature were quite frequent, and were most pronounced when the upper air currents were from south-east to south-west. Clouds, as a rule, caused a decrease in the rate of temperature fall, sometimes so decided as to result in an actual temperature inversion. A series of observations was made at Pierre, South Dakota, during the winter of 1898–99, and a cursory examination of the records there made showed such persistent temperature inversions during periods of cold weather as to furnish convincing evidence that during a cold wave the stratum of cold air is not much over one mile in height, and frequently but little over half a mile.

The relative humidity at and above the earth's surface differed but little, and, generally speaking, the upper air percentages were the lower. The mean results were 60

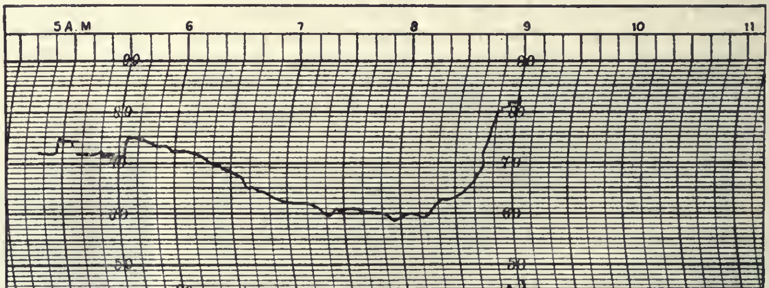

FIG. 3.—Record obtained at Arlington, Virginia, on June 14, 1898.

and 58 per cent. respectively, a difference of 2 per cent. There were, however, some marked differences at individual stations. At Washington, D.C., it was 14 per cent.; at Omaha, Nebraska, 29 per cent.; and at Spring-

field, Illinois, 21 per cent. At Fort Smith, Arkansas, the difference was 12 per cent., but with reversed conditions, the upper air humidity being the higher.

The vapour pressures were compared with others obtained at various times at equal altitudes by means of balloons and mountain observations, and found to be somewhat lower. The average value was 59 per cent., as compared with 68 for the balloon and 66 for the mountain observations. In these data the vapour pressures were represented in percentages obtained by the formula $\frac{p}{p^o}$, p representing the vapour pressure at any given altitude, and p^o that observed simultaneously at the earth's surface.

Differences in wind direction above and at the surface were for the most part confined to a deflection toward the right at the kite. This deflection frequently increased with the altitude, but rarely exceeded 90 degrees. In some few instances, chiefly during unsettled weather, the deflection was toward the left, but not to any great extent.

At the present time efforts are being made to obtain a more improved and satisfactory vehicle for the meteorograph. If such an one can be devised, it is yet possible that the desire of the forecaster will finally be gratified with great resultant benefit both to the cause of science and to the world at large. H. C. FRANKENFIELD.

THE PRESENT CONDITION OF THE INDIGO INDUSTRY.

SINCE a previous article upon the above subject (November 1) was written, a report of the opening of the Hofmann House in Berlin has appeared in the *Times*. At the opening ceremony Prof. von Baeyer and Dr. Brunck delivered lectures upon the synthetical production of indigo. Von Baeyer's lecture dealt chiefly with the theoretical side of the question, while that of Dr. Brunck, who is one of the managing directors of the Badische Anilin und Soda Fabrik, dealt more upon the manufacturing side. As the work of von Baeyer is so well known and was referred to in the previous article, attention will only be drawn to the extremely interesting speech of Dr. Brunck.

In the first place, Dr. Brunck drew attention to the advantages of synthetic over natural or vegetable indigo, owing to its uniformity of composition, fine state of division, ready reducibility, &c. He claimed that a much less skilled operator may be employed in manipulating the dye bath than when natural indigo is used. He then went on to describe the prejudice which the synthetical indigo ("indigo pure") had to contend with when it was first placed on the market in 1897; it being stated by some that it was merely specially refined natural indigo, and by others that it was a substitute for indigo. It is extraordinary how difficult it is to make the public believe that it is possible to prepare in the laboratory a product which is identical in *every* respect to one which is of vegetable origin. In the case of indigo, however, there is perhaps some excuse, because the manufacturers of coal-tar products have often brought out colours which dye practically the same shades as indigo, but though not readily distinguished from it even by experts, have lacked one of the chief characteristics of indigo—fastness. But notwithstanding prejudice and keen competition, the development of the manufactory has been enormous. Dr. Brunck states that about 900,000*l.* has been invested in the indigo department of the Badische Company, and that the quantity of indigo now annually manufactured by this company alone would require the cultivation of nearly 250,000 acres of land in India.

The method of manufacture employed by the Badische Company is that of Heumann, in which phenylglycine-ortho-carboxylic acid (anilido-acetic acid) is fused with caustic soda (*c.f.* NATURE, this volume, p. 9). When this process was first discovered, the cost of the out-going products was so great that indigo so prepared could not compete with the natural product. *The Badische Company employ more than 100 highly-trained research chemists;* to some of these the work of endeavouring to elucidate the problem, how to manufacture phenylglycine-ortho-carboxylic acid cheaply, was entrusted. Taking naphthalene, which is obtained in enormous quantities from coal tar, as starting product, the following process was worked out. The naphthalene is oxidised by highly concentrated sulphuric acid in presence of mercury or mercury salts, with production of phthalic acid. The phthalic acid is then, by a series of reactions, converted into anthranilic acid which, when combined with monochloracetic acid, produces phenylglycine-ortho-carboxylic acid. During the oxidation of naphthalene with sulphuric acid large quantities of sulphur dioxide are produced, the loss of which would be a very serious expense. In preparing indigo upon the scale in which it is now manufactured, from 25,000 to 30,000 tons of sulphur dioxide are produced annually. But this is not lost; it is mixed with air and passed over heated oxide of iron, and is thus by catalytic action converted into sulphuric anhydride, and this by the action of water into sulphuric acid. Chlorine is required in order to prepare chloracetic acid, and caustic soda to fuse the phenylglycine-ortho-carboxylic acid. These two products are obtained by the electrolysis of sodium chloride. As, however, the chlorine as it is first produced is not sufficiently pure, it is purified by condensing it to the liquid condition. Attention has been drawn to the details of the manufacturing process, in order to show what a determined and powerful competition the Indian indigo producer has to face.

Synthetical indigo is being used in this country, but there is a considerable difference of opinion as to whether it is as easy to dye with the artificial as with the natural product. Some dyers state that there is a difficulty in obtaining the requisite bloom and that, therefore, materials dyed with it have a flat or dead appearance; other operators seem to find no such difficulty. Practically the only drawback to materials dyed with indigo is that the dye is inclined to rub. Some dyers say that goods dyed with synthetical indigo rub more than when dyed with the vegetable indigo. This, again, is denied by others. There is also said to be a difficulty in reducing synthetical indigo. In print-work synthetical indigo certainly appears to possess an advantage, owing to its fine state of division and to the fact of its containing no foreign matter which might scratch and injure the rollers. Before natural indigo can be employed, it is necessary to have it in an exceedingly fine state of division, and in order to ensure this it is usually ground in a mill with water for several days. The artificial product, on the other hand, is sent into the market as a very fine powder or in the form of a paste. One drawback to natural indigo is the varying amounts of indigotin which different samples contain. Artificial indigo contains not only a very high percentage of indigotin, but practically no foreign matter.

Dr. Brunck is sanguine that the synthetical product will shortly overcome all competition and drive the natural product from the market; and in his address, with a *disinterestedness* which cannot but be admired, advises the Government of India to ascertain in what manner the land which has been employed for growing indigo may be best cultivated. If the advice of Dr. Brunck is taken, there will be no doubt as to the success of the artificial indigo. As showing the vast importance of the question to India, the following statistics are given. In Northern Behar there are from 250,000 to 300,000 acres of land devoted to the cultivation of indigo,

and nearly one and a half million people are employed in the industry, while three years ago the capital invested in this province was estimated at over 4,000,000*l*. The land under cultivation in Bengal was, in 1899, estimated at 452,700 acres. There seems at last to be some movement among the dry bones; the Indigo Planters' Association have employed Mr. Rawson, who is an expert upon the chemistry of dyeing, to endeavour to improve the process of manufacturing indigo, and appeals are made to the Government for help. The Government is doing its part, and has ordered that all blue cloth supplied to the Army and Navy Clothing Departments shall be dyed with *natural* indigo. At the present time the price of natural and synthetic indigo is almost the same. What will the Government do if the price of synthetic indigo becomes much less than that of natural indigo? Sir William Hudson, in August of this year, applied to the Government for a loan for a scheme of sugar cultivation, suggesting that indigo and sugar-cane should be grown in rotation. The Government, although not able to accede to his request, has sanctioned a committee to inquire into the possibilities of establishing the sugar industry in Behar.

When attention is drawn to the perilous position of the Indian indigo industry, letters are written to the papers by those connected with the production of indigo, making light of the danger, and referring to the "*real* indigo dye and German imitation." But, as Mr. Rawson, who at least is not likely to overrate the artificial indigo, said in his admirable lecture, delivered before the Society of Arts at the end of March, "all chemists who have studied the question agree that synthetic indigo is *identically* the same compound as the indigotin of natural indigo"; and again, "Providing the synthetic dye can be produced in sufficient quantity, the whole question of artificial *versus* natural indigo will resolve itself into one of cost. The Badische Company have spent nearly a million pounds in improving the manufacture of artificial indigo; at Höchst, the "Farben Fabrik" is also manufacturing artificial indigo, though at present they are only supplying the German market. In a letter to the *Times* on April 24, Prof. Armstrong asks, "Have we spent 5000*l*. in the endeavour to set our Indian indigo house in order?" For every British chemist employed it is safe to say the Germans are employing fifty; for every pound spent they are spending thousands. Is it not time to appoint a committee or commission of experts to see whether it may not be possible to increase the yield and quality of the indigo produced, and at the same time to produce it more economically?

F. MOLLWO PERKIN.

NOTES.

PROF. POINCARÉ has been elected a foreign member of the Munich Academy of Sciences.

PROF. KLEIN has been elected a correspondant of the Paris Academy of Sciences, in the section of mineralogy. Prof. Haller has been elected a member of the Academy in succession to the late M. Grimaux.

THE Rammelsberg Memorial Lecture will be delivered at the Chemical Society by Prof. H. A. Miers, F.R.S., on Thursday, December 13.

WE notice in *Science* the announcement that Prof. Schiaparelli retired on November 1 from the directorship of the observatory at Milan, where he has been at work for the past forty years. His successor is Prof. Celoria, heretofore assistant astronomer at the observatory.

AT the annual meeting of the Royal Geological Society of Cornwall, Dr. Le Neve Foster was presented with the William Bolitho gold medal in recognition of the distinction which he has attained as a mineralogist and also of the great services rendered by him to the society as curator during the period when he held the appointment of inspector of mines for Cornwall and Devon.

IT is reported that M. Daniel Osiris, a Greek millionaire residing in Paris, has instituted a prize on the lines laid down by Mr. Nobel, though his offer is for Frenchmen only, except in a Paris Exposition year, when it becomes universal. He has set aside a sum to be awarded every three years in perpetuity to the discoverer, inventor or producer of the most noteworthy idea or object for the benefit of humanity. The prize is to be never less than 100,000 francs, and may be double that sum.

A RUMOUR, which we profoundly regret, has reached us to the effect that, owing to increasing financial difficulties, the Government of Jamaica, W.I., is obliged to retrench in the work of the museum, and that the curator, Dr. J. E. Duerden, A.R.C.S. (London), will be shortly returning to England. During his appointment in the Colony, Dr. Duerden has carried out investigations on the local aboriginal Indian remains and in marine zoology. Among the important results obtained may be mentioned the discovery of the free-swimming female medusoids of Millepora; the discovery that the addition of new mesenteries and septa in the coral Porites takes place in a bilateral manner at the dorsal or ventral aspect of the polyp, recalling the method probably followed in the ancient Rugose corals; the establishment of the fact that the order of septal formation in most Madreporaria follows closely the law ascertained long ago by Prof. Lacaze-Duthiers for the cycles of tentacles in Actiniæ. Can nothing be done to save the Colony from the opprobrium which must follow the forsaking of pure science?

THE value of anti-plague serum is a very vexed question. Yersin in 1896, in China, claimed a mortality of only 7·6 per cent. in twenty-six cases treated with his serum, and the same observer in 1897, in India, using Roux's serum, stated that the mortality was only 49 per cent., as compared with 80 per cent. among the cases not treated with serum. The Indian medical officers and the German Commission, however, reported unfavourably upon his results, and the serum treatment of plague has not been adopted in India. Clemow, in India in 1899, employed both Yersin's and Lustig's sera, but was unable to observe any good results from the use of either. On the other hand, in the outbreak of plague in Oporto last year, Calmette and Salimbeni claim to have obtained excellent results with the use of serum prepared at the Pasteur Institute by the most recent method—viz. by treating horses with increasing doses, first of dead and afterwards of living cultures, of plague bacilli, administered by intravenous injection during a period of five or six months. The mortality of the cases treated with serum was 15·3 per cent., as against 63·7 per cent. for the untreated cases. Calmette holds that for successful treatment the anti-plague serum must be administered in large doses, intravenously to commence with, and afterwards by repeated subcutaneous injection, early treatment being essential. The experimental results are distinctly in favour of the value of anti-plague serum both as a preventive and as a curative agent.

MR. R. HEDGER-WALLACE, formerly of the Department of Agriculture, Victoria, is giving a course of lectures on the "First Principles of Colonisation and Plantation," at the Gardens of the Royal Botanic Society of London. The remaining lectures will be delivered on November 30 and December 7 at three o'clock.

IN consequence of the annual dinner of the Institution of Electrical Engineers being fixed for Monday, December 3, the second lecture of Prof. Fleming's Cantor course at the Society of Arts, on "Electric Oscillations and Electric Waves," announced

for that date will be postponed until the following day, Tuesday, December 4, to suit the convenience of members and others who might be prevented by the dinner from attending it.

THE Council of the Institution of Engineers and Shipbuilders in Scotland is arranging an International Engineering Congress, under the presidency of Lord Kelvin, in connection with the Glasgow International Exhibition of 1901. The leading engineering and kindred societies have already accorded their hearty support to the congress. An influential London Committee has been formed, and the congress gives every promise of being a success.

SIR WILLIAM MACCORMAC, president of the Royal College of Surgeons of England, has received the Royal licence and authority that he may accept and wear the Cross of Commander of the Legion of Honour, conferred upon him by the President of the French Republic, in recognition of services which he rendered to the French wounded during the war of 1870–71, as well as to the International Congress of Medicine held during the recent Paris Exhibition.

AT the end of this year Dr. H. R. Mill will retire from the post of librarian to the Royal Geographical Society, and will be succeeded by Mr. E. Heawood. The scientific appointment which he has accepted will enable him to devote more attention to the investigation of meteorology and oceanography in their relation to the configuration of the ground than has been possible during his nine years' librarianship.

AT the Imperial Institute on Monday an illustrated public lecture was delivered by Mr. Clement L. Wragge, Government Meteorologist of Queensland, on "The Work of the Queensland Weather Bureau, in its Relation to the Natural Resources and Commerce of Australasia." The work of the Queensland Weather Bureau is divided into two main parts, (1) the investigation of local climates, climatology, and (2) forecasting the weather. In speaking of the daily forecasting service, Mr. Wragge said that by an Inter-colonial system of exchange of data his Bureau is daily placed in possession of barometric and other meteorological readings from every part of Australasia, and the forecasts prepared therefrom are published in the principal daily Australasian papers. He advocated the American system of hoisting flags of different designs and colours at the telegraph offices of every town. The comparison of simultaneous observations of the upper regions of the air, made at mountain observatories, with those made at the nearest point on the sea level, are of great value, as meteorologists are thus enabled to obtain practically vertical sections of the atmosphere.

WE have received the twenty-second report of the Deutsche Seewarte, Hamburg, referring to the work of that important institution for the year 1899. The meteorological services of Germany are divided into two parts. The Central Office at Berlin, whose report we noticed in our issue of last week, deals with the climatological observations over the whole Empire, in co-operation with the various States of Germany; while the Hamburg Office deals with everything appertaining to maritime meteorology, including storm warnings, and for this purpose has under its control a number of independent stations, especially along the sea coasts. In carrying out these objects, Dr. Neumayer has the assistance of Drs. Köppen, van Bebber and other well-known men of science. In glancing through the report, one is at once struck by the persistent and successful endeavours to collect observations made at sea; the complete logs and abstract books received during the year from the ships of the Navy and Mercantile Marine numbered no less than 818. For the supply of log-books the consuls in various parts of the world, including this country, act as agents of the Seewarte. The results are published in valuable tables and charts, which are frequently referred to in these columns. For the purpose of issuing weather forecasts and storm warnings the institution is in daily telegraphic communication with all the meteorological services of Europe; upwards of 3000 telegraphic storm warnings were issued to various stations during the year 1899, and the daily and ten-daily weather reports furnish most trustworthy and useful information, the latter relating to weather conditions over an area extending from North America across the North Atlantic, and far into the continent of Asia.

SOME interesting particulars respecting the growth of the acetylene gas industry are given in a recent report by the British Consul at Stuttgart. Calcium carbide has been known to chemists as an interesting chemical compound for several years, but until recently it was practically unknown to the public. Now its production is one of the most important chemical industries. Germany was foremost to recognise the new illuminant, and it has secured the principal place in its production. At present there are at least 200,000 jets of acetylene gas in use in the country, and it is, the Consul says, impossible to predict the result of the competition between it and its rival illuminants. Probably petroleum will suffer most; coal gas will be superseded to a great extent, especially in lighting small towns, but electricity will not be appreciably affected. No other branch of industry can point to such a large and steady increase in the number of patents, showing that it has encouraged great fertility of invention. Besides producing it at home, German capital has gone abroad to produce carbide, especially to Norway and Switzerland. One of the greatest successes of the industry has been its application to the lighting of railway carriages on German Government lines. During the current year the consumption of carbide in the country is estimated at 17,000 tons, equal in illuminating power to about seven millions of gallons of petroleum. Thirty-two small towns, with populations up to 5000, are lighted by acetylene, and many more contemplate its adoption; and the progress of the system of lighting, says the Consul, is "another striking instance of the manner in which the magnificent system of technical education has prepared the way for the introduction of new scientific achievements." The economic importance of the industry appears from the fact that Germany annually pays about five millions sterling to the United States for petroleum, while acetylene is a purely German industry, carbide being manufactured in the country, which possesses in various parts all the necessary raw materials.

WE have received a copy of an illustrated memoir by Signor Rina Monti, published in the *Memorie* of the Royal Institute of Lombardy (vol. xix. pt. i.), detailing the results of experiments on the power of regeneration displayed by marine planarians. It was found that if one of these creatures was cut into two or more portions by transverse section, as many complete individuals were produced.

To the November number of the *Zoologist* Mr. A. H. Meiklejohn contributes a paper on the origin and meaning of the names of British birds, a subject which, according to the author, has hitherto received but little attention. "In most birds' names," he writes, "special stress is invariably laid on some well-known or easily distinguished peculiarity either in cry, flight or appearance." Names from the cry, such as pipit, crake, cuckoo, hoopoe and kittiwake, are especially numerous. To the origin of some, like gull, auk and garganey, there is no clue.

SINCE the publication, some years ago, by Prof. D'Arcy Thompson, of a paper on the affinities of the Eocene American cetacean, commonly known as Zeuglodon, very little advance in our knowledge of the genus has taken place. It is, therefore, satisfactory to find Mr. F. A. Lucas, in the *Proceedings* of the U.S. Museum (vol. xxiii. pp. 327–331), giving an account of the pelvis and

thigh-bone. Both these bones are relatively small, and in life were probably completely buried in the flesh. Although the relationship may be remote, the author considers that Zeuglodon was certainly related to the seals; adding that it probably represents a side branch of the ceto-phocic stock which left no descendants. It is also mentioned that the abundance of its remains in certain districts of the United States has been much exaggerated.

PROF. W. A. HERDMAN has drawn up a scheme of investigations for submission to the Committee of the Lancashire and Western Sea Fisheries. These investigations, it is suggested, should be carried out systematically by the Committee's new steamer, commencing with the new year. The questions as to whether a particular fishery is on the wane or the increase, or whether "nurseries" are already overstocked with young fish or stand in need of replenishing by artificially hatched fish, can only, according to Prof. Herdman, be solved by means of accurate information connected with the abundance, movements and life-histories of the species of fish concerned; and such information can only be acquired by a practical scientific investigation of our seas. The tables drawn up for recording the observations taken during each cruise seem admirably adapted for their purpose. It is proposed that a certain amount of the steamer's time should be devoted to the taking of regular periodic observations at fixed points according to the plan of these tables.

WE have received from the publishers, Messrs. Gurney and Jackson, a copy of the second edition of Mr. H. Goss's valuable pamphlet on the "Geological Antiquity of Insects," the first edition of which was noticed in these columns. In the preface the author expresses regret that he has had neither time nor energy to incorporate the new matter which has been published since the appearance of the first edition, so that the present issue is mainly a reprint of the latter.

MR. A. S. PACKARD describes some tracks of Crustaceans found in rocks of the Chemung stage (Upper Devonian), and in upper Carboniferous of Pennsylvania and elsewhere (*Proc.* Amer. Acad., July 1900). These tracks he attributes to Limuloids akin to the Carboniferous genus Prestwichia. Mr. Packard also describes a new fossil crab (*Cancer proavitus*), from the Miocene of Gay Head, Martha's Vineyard. He remarks that the extinct species appears to be the stem or ancestral form from which have descended the two species now living in the waters of Vineyard Sound.

THE geological section of the Leicester Literary and Philosophical Society is doing excellent work under the chairmanship of Mr. H. Alfred Roechling. Excursions have this year been made to Atherstone, Polesworth, Ashby-de-la-Zouch and other places, concerning which concise reports have been printed, together with sections and geological maps (on a scale of two inches to a mile). These maps and sections are the work of Mr. C. Fox Strangways, who has acted as geological leader on many of the excursions.

IN the *Astrophysical Journal* (vol. xii. pp. 167–175), Prof. H. Crew describes some very interesting experiments he has recently made on the differences in the spectra of various metals when the arc producing the light was surrounded by ordinary air or hydrogen. The investigation was undertaken in the hope that the new condition might have some selective effect on the spectrum lines, and thereby facilitate their grouping into series. The arc was produced in a brass hood made in two halves; into one of these the two electrodes were fitted by insulated bearings, provision being made for one of the electrodes being rotated from outside. The opposing edges of the two hemispheres were then screwed together, and a gas-tight joint obtained. Opposite the space between the poles, the hood was provided with an opening carrying a brass tube some 12 inches long, having at its outer end a quartz lens which served to project an image of the enclosed arc on to the slit of a concave Rowland spectrograph of 10-feet radius. The hydrogen was supplied from three large electrolytic cells, and, after passing through a drying tube, was allowed to continually pass through the brass hood, the surplus being ignited at a stopcock. The first indication of the effect of the hydrogen was to materially diminish its intensity, so much so that in some cases the exposure had to be from five to one hundred times that necessary in air only. In addition, there is a most conspicuous change of relative intensity among the lines of any one substance. Tables are given of the lines affected in the cases of magnesium, zinc and iron. In magnesium, the characteristic line at $\lambda 4481$ has an intensity in hydrogen ten times as great as in air, this change being similar to that obtained in passing from the arc to the induction spark. In the case of iron many lines are greatly enhanced in intensity, but these are not the same lines which are enhanced in substituting the spark for the arc condition; but the author states that all lines in the arc spectrum which are affected by the hydrogen atmosphere, whether enhanced or diminished in intensity, belong to the spark spectrum also. On the other hand, the lines which belong to Kayser and Runge's series are unaffected by the change from air to hydrogen.

MESSRS. PERKEN, SON AND CO., LTD., have just issued a new catalogue of photographic apparatus, magic lanterns and accessories.

FOLLOWING the example of Cornell University, the New Mexico Normal University has commenced the publication of instructive bulletins to encourage interest in nature study. The subjects of the first two bulletins are house-flies and pigments.

IN his letter on the optics of acuteness of sight (p. 83), Dr. A. S. Percival pointed out that as the angle subtended by Jupiter's edge and his first satellite at the observer's eye is greater than one and a half minutes of arc, there is no reason why the four satellites should not be seen by the naked eye. The angle is 1′33″, and not 1·33″ as it was printed.

WE have received from the firm of Gebrüder Borntraeger, Berlin (London: Williams and Norgate), the second fasciculus of the second volume of "Symbolae Antillanae seu fundamenta Florae Indiae occidentalis," edited by Herr J. Urban. The new part deals with the Cyperaceæ, Acanthaceæ, new Lauraceæ and Bromeliaceæ, and new and little known Leguminosae.

PROF. CORFIELD'S Harveian lectures on "Disease and Defective House Sanitation," of which translations into French and Hungarian have already been published by the Royal Society of Public Health of Belgium and the Hungarian Society of Public Health respectively, have now been translated into Italian by Dr. Soffiantini, of Milan, and are being published, with illustrations, in *Il Monitore Tecnico*.

MESSRS. J. AND A. CHURCHILL have published a fourth edition of Dr. E. H. Starling's "Elements of Human Physiology." As an introduction to the larger text-books the volume is admirable, and it has proved a serviceable guide to many students since the original volume was published in 1892. A review of the book appeared in NATURE eight years ago (vol. xlvii. p. 146), and we are glad to know that the merits which have made it successful were then fully recognised.

THE second fasciculus of the first volume of the "Conspectus florae graecae," by Dr. E. de Halácsy, has been published by Mr. W. Englemann, of Leipzig (London: Williams and Norgate). Nearly a century has elapsed since the appearance of

Sibthorp and Smith's "Prodromus florae graecae," and other works on the subject have been issued; but the conspectus now in course of publication will be the first attempt to give anything like a complete account of the flora of Greece, inclusive of Epirus, Crete and neighbouring islands. The work will be entirely in Latin, and will be completed in from eight to ten parts, each of about 160 pages. It is estimated that about five years will elapse before the last part has appeared.

A fifth edition, rewritten and enlarged, of the "Handbook of Practical Botany," translated by Prof. W. Hillhouse from Prof. Strasburger's "Praktikum," has been published by Messrs. Swan Sonnenschien and Co., Ltd. The translation is based upon the third German edition of Prof. Strasburger's well-known work, issued in 1897. A number of new figures have been added, and the notes introduced by Prof. Hillhouse in earlier editions have now been incorporated in the text. The bibliographical notes formerly appended to the chapters have been omitted. For nearly fourteen years Prof. Hillhouse's translation of Prof. Strasburger's text-book has been in use in botanical laboratories, and has shown many students the way to become acquainted with the broad facts of scientific structural botany and the methods of microscopical work. In its revised form the book will be welcomed by all who are interested in the practical study of botany.

The publication of a bibliography, guide and index to bacteriological literature has been commenced in *The Scientific Roll*, conducted by Mr. Alexander Ramsay. The first title included in the part of the general bibliography just issued is "Arcana naturæ detecta," by Leeuwenhoek (1680), and the list extends to 1875 and includes one hundred and one papers published in that year. The works are arranged alphabetically, according to authors. Though the list is not exhaustive it will provide people interested in bacteria with a ready means of finding what has been published on bacteriological subjects, and of tracing the growth of the science. Mr. Ramsay invites authors to send him copies of their papers so that he may make the bibliography as complete as possible. The publisher of the list is Mr. R. L. Sharland, 38, Churchfield-road, Acton, London, W.

A work of interest to students of ethnology, containing the results of the journey to Algeria made by Messrs. D. Randall-MacIver and A. Wilkins, is about to be published by Messrs. Macmillan and Co., under the title of "Libyan Notes." The object of the expedition was to establish if possible any trace of a connection between the Berber tribes and Egypt—a trace finally discovered in the pottery of the Kabyles—but incidentally the writers undertook and recorded a general investigation of the indigenous white race of Northern Africa known to Rome as the Numidians, Gœtulians or Mauri—who figure as a white race on Egyptian monuments as far back probably as 1300 B.C. Thus in addition to the special chapters on the Kabyle pottery and the evidences of a Libyo-Egyptian connection, the book will contain remarks on the Berber history, their language, their interesting political and social organisation; detailed descriptions both of the Aurès and Kabylia, their inhabitants and the local industries; observations and statistics on the physical type of the Berbers based on measurements; and finally some account of the rude stone monuments of Algeria.

The additions to the Zoological Society's Gardens during the past week include a Bonnet Monkey (*Macacus sinicus*) from India, presented by Mrs. Henry Lazarus; a Rhesus Monkey (*Macacus rhesus*) from India, presented by Mr. H. A. Loop; an Egyptian Jerboa (*Dipus aegyptius*) from North Africa, presented by Mr. K. Riccardo; four Black-backed Jackals (*Canis mesomelas*) from South Africa, presented by Mr. J. E. Matcham; an African Civet Cat (*Viverra civetta*) from West Africa, presented by Mr. R. H. Brady; a Puffin (*Fratercula arctica*), European, presented by Mr. E. T. Norris; a Common Roe (*Capreolus caproea*, albino), European; a One-wattled Cassowary (*Casuarius uniappendiculatus*) from New Guinea, a Yellow-rumped Parrakeet (*Platycercus flaveolus*) from Queensland, an Ocellated Monitor (*Varanus ocellatus*) from East Africa, five Blue Lizards (*Gerrhonotus coeruleus*) from Western North America, three Undulated Lizards (*Sceloporus undulatus*) from South-east United States, deposited; an Axis Deer (*Cervus axis*), born in the Gardens.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in December.

Dec. 4. 18h. 41m. to 18h. 45m. Moon occults 13 Tauri (mag. 5·4).
5. 6h. 11m. to 6h. 46m. Moon occults ω^2 Tauri (mag. 4·6).
5. 16h. 5m. to 17h. 0m. Moon occults DM + 20°, 785 (mag. 5·8).
7. 15h. Mercury at greatest elongation, 20° 50′ W.
8. 13h. 32m. to 14h. 37m. Moon occults DM + 17° 1596 (mag. 5·6).
10. 8h. 56m. to 9h. 52m. Moon occults κ Cancri (mag. 5·0).
10–12. Epoch of Geminid meteoric shower (Radiant 108° + 33°).
11. 12h. 36m. Minimum of Algol (β Persei).
12. 13h. Mars in conjunction with moon. Mars 8° 26′ N.
13. 21h. Jupiter in conjunction with the sun.
14. 9h. 25m. Minimum of Algol (β Persei).
15. Venus. Illuminated portion of disc = 0·836.
Mars. ,, ,, ,, = 0·907.
16. Saturn. Outer minor axis of outer ring = 15″·40.
17. 6h. 14m. Minimum of Algol (β Persei).
18. 19h. Venus in conjunction with the moon. Venus 2° 19′ N.
19. 16h. Neptune in opposition to the sun.
20. 0h. Mercury in conjunction with moon. Mercury 0° 2′ N.
26. Eros makes nearest approach to the earth.
26. 7h. 42m. to 8h. 33m. Moon occults 51 Aquarii (mag. 5·8).
29. 1h. Saturn in conjunction with sun.

New Variable Stars.—*Cygnus.*—Herr T. Köhl, writing from an observatory at Odder, Denmark, to the *Astronomische Nachrichten* (Bd. 154, No. 3673), draws attention to the variability of the star B.D. + 46°·2970, whose co-ordinates are

$$\left.\begin{array}{l}\text{R.A.} = 20\text{h. } 28\text{m. } 33{\cdot}7\text{s.}\\ \text{Decl.} = +46^\circ\ 4'{\cdot}2\end{array}\right\}(1855).$$

A note by Herr E. Hartwig suggests that the period of this variable is more than a year.

Aquila.—Dr. T. D. Anderson, in the same journal, announces the variability of the star B.D. + 9°·4205, having the position

$$\left.\begin{array}{l}\text{R.A.} = 19\text{h. } 33\text{m. } 48{\cdot}2\text{s.}\\ \text{Decl.} = +9^\circ\ 35'{\cdot}4\end{array}\right\}(1855).$$

Using four neighbouring stars for comparison, the following values were obtained:—

	Mag.
1900 Sept. 18 =	9·2
24 =	9·2
Oct. 1 =	9·4
25 =	10·0
Nov. 9 =	10·6

Pegasus.—Dr. Anderson also finds the star A.G. Leipzig I. 8381 to be variable. Its position is

$$\left.\begin{array}{l}\text{R.A.} = 21\text{h. } 6\text{m. } 15{\cdot}0\text{s.}\\ \text{Decl.} = +12^\circ\ 12'\ 26''\end{array}\right\}(1855).$$

The following estimations of its magnitude have been made:—

	Mag.
1900 Sept. 26 =	9·1
Oct. 27 =	9·5
Nov. 10 =	10·1

EPHEMERIS FOR OBSERVATIONS OF EROS.—The following abridged ephemeris will serve for finding the planet during the month of December :—

Ephemeris for 12*h*. *Berlin Mean Time*.

1900.		R.A. h. m. s.		Decl. ° ′ ″

DISTRIBUTION OF MINOR PLANETS.—M. Freycinet has a further article in the *Comptes rendus* (vol. cxxxi. pp. 815-821), in which he discusses the distribution of the zone of asteroids more critically than in his previous paper in *Comptes rendus*, cxxx. pp. 1145-1154. On the assumption that these small bodies are the product of disruption of a former ring of matter revolving round the central body, he calculated the mean eccentricities of the several rings into which it might be expected to divide. On examination of the elements of 428 of the planets, it has been possible to divide them into eight groups, the members of each group having similar eccentricity and inclination of orbit. The numbers of separate bodies in each zone vary greatly—from 1 to 170. The mean thickness of the rings is 0·278, the radius of the earth's orbit being taken as unit, the individual rings varying from 0·22 to 0·36. In each ring the mean eccentricity of the members situated in the inner or inferior half is greater than that of the members occupying the superior or outer half; and comparing two rings, it is found that the mean eccentricity of the planets in the inferior part of the outer ring is greater than that of those occupying the superior part of the inner ring. In one ring—the fifth—consisting of 69 planets, the mean eccentricities of the two halves are identical, and it will be interesting to examine the places occupied by asteroids discovered in the future as to their effect on the constants of this region of the swarm.

THE NOVEMBER METEORS.—In the *Comptes rendus* (vol. cxxxi. pp. 821-825) Dr. Janssen describes the special preparations made for observing, from balloons, the meteors expected during the past month. A few Leonids were seen, but no indication of any special fall. In the description of the ascents, mention is made of the observers having to pass through several cloud belts, suggesting that in future an altitude of some 6000 metres should be attained to ensure more certainty of a clear sky.

M. Deslandres also gives, in the same issue (pp. 826-7), the results of the observations made at the Meudon Observatory. They were both visual and photographic, the latter being made with six cameras having apertures from 6 to 2 inches. All were carried by a single equatorial mounting so as to be under the control of one observer.

On the night of November 14, from 9h. 30m. to 1h., traces of 16 meteors were secured, of which 6 were Leonids, 5 Andromedes and 2 sporadie. On the night of the 15th, after 9h. 30m. 5 traces were obtained, 3 of which were Leonids.

HUXLEY'S LIFE AND WORK.[1]

II.

ANOTHER remarkable side of Huxley's mind was his interest in and study of metaphysics. When the Metaphysical Society was started in 1869, there was some doubt among the promoters whether Huxley and Tyndall should be invited to join or not. Mr. Knowles was commissioned to come and consult me. I said at once that to draw the line at the opinions which they were known to hold would, as it seemed to me, limit the field of discussion, and there would always be doubts as to when the forbidden region began ; that I had understood there was to be perfect freedom, and that though Huxley's and Tyndall's views might be objectionable to others of our members, I would answer for it that there could be nothing in the form of expression of which any just complaint could be made.

The society consisted of about forty members, and when we consider that they included Thompson, Archbishop of York, Ellicott, Bishop of Gloucester and Bristol, Dean Stanley and Dean Alford as representatives of the Church of England ; Cardinal Manning, Father Dalgairns and W. G. Ward as Roman Catholics ; among statesmen, Gladstone, the late Duke of Argyll, Lord Sherbrooke, Sir M. Grant Duff, John Morley, as well as Martineau, Tennyson, Browning, R. H. Hutton, W. Bagehot, Frederic Harrison, Leslie Stephen, Sir J. Stephen, Dr. Carpenter, Sir W. Gull, W. R. Greg, James Hinton, Shadworth Hodgson, Lord Arthur Russell, Sir Andrew Clark, Sir Alexander Grant, Mark Patteson, and W. K. Clifford, it will not be wondered that I looked forward to the meetings with the greatest interest. I experienced also one of the greatest surprises of my life. We all, I suppose, wondered who would be the first President. No doubt what happened was that Roman Catholics objected to Anglicans, Anglicans to Roman Catholics, both to Nonconformists ; and the different schools of metaphysics also presented difficulties, so that finally, to my amazement, I found myself the first President ! The discussions were perfectly free, but perfectly friendly ; and I quite agree with Mr. H. Sidgwick, that Huxley was one of the foremost, keenest and most interesting debaters, which, in such a company, is indeed no slight praise.

We dined together, then a paper was read, which had generally been circulated beforehand, and then it was freely discussed, the author responding at the close. Huxley contributed several papers, but his main contribution to the interest of the Society was his extraordinary ability and clearness in debate.

His metaphysical studies led to his work on Hume and his memoirs on the writings of Descartes.

One of his most interesting treatises is a criticism of Descartes theory of animal automatism. Descartes was not only a great philosopher, but also a great naturalist, and we owe to him the definite allocation of all the phenomena of consciousness to the brain. This was a great step in science, but, just because Descartes' views have been so completely incorporated with everyday thought, few of us realise how recently it was supposed that the passions were seated in the apparatuses of organic life. Even now we speak of the heart rather than the brain in describing character.

Descartes, as is known, was much puzzled as to the function of one part of the brain—a small, pear-shaped body about the size of a nut, and deeply seated. Known as the pineal gland, he suggested that it was the seat of the soul ; but it is now regarded, and apparently on solid grounds, as the remains of the optic lobe of a central eye once possessed by our far-away ancestors, and still found in some animals, as, for instance, in certain lizards. Descartes was much impressed by the movements which are independent of consciousness or volition, and known as reflex actions—such, for instance, as the winking of the eye or the movement of the leg if the sole of the foot is touched. This takes place equally if, by any injury to the spinal marrow, the sensation in the legs has been destroyed.

Such movements appear to be more frequent among lower animals, and Descartes supposed that all their movements might be thus accounted for—that they were, like the movements of sensitive plants, absolutely detached from consciousness or sensation, and that, in fact, animals were mere machines or automata, devoid not only of reason, but of any kind of consciousness.

It must be admitted that Descartes' arguments are not easy to disprove, and no doubt certain cases of disease or injury—as, for instance, that of the soldier described by Dr. Mesnet, who, as the result of a wound in the head, fell from time to time into a condition of unconsciousness, during which, however, he ate, drank, smoked, dressed and undressed, and even wrote—have supplied additional evidence in support of his views. Huxley, while fully admitting this, came, and I think rightly, to the conclusion that the consciousness of which we feel certain in ourselves must have been evolved very gradually, and must therefore exist, though probably in a less degree, in other animals.

[1] The first "Huxley Memorial Lecture" of the Anthropological Institute, delivered on November 13, by the Rt. Hon. Lord Avebury, F.R.S., D.C.L., LL.D. Continued from p. 96.

No one, indeed, I think, who has kept and studied pets, even if they be only ants and bees, can bring himself to regard them as mere machines.

The foundation of the Metaphysical Society led to the invention of the term "Agnostic."

"When I reached intellectual maturity," Huxley tells us, "and began to ask myself whether I was an atheist, a theist or a pantheist, a materialist or an idealist, a Christian or a freethinker, I found that the more I learned and reflected, the less ready was the answer; until, at last, I came to the conclusion that I had neither art nor part with any of these denominations except the last. The one thing in which most of these good people were agreed was the one thing in which I differed from them. They were quite sure they had attained a certain "gnosis"—had, more or less successfully, solved the problem of existence; while I was quite sure I had not, and had a pretty strong conviction that the problem was insoluble . . . ."

These considerations pressed forcibly on him when he joined the Metaphysical Society.

"Every variety," he says, "of philosophical and theological opinion was represented there, and expressed itself with entire openness; most of my colleagues were "ists" of one sort or another; and, however kind and friendly they might be, I, the man without a rag of a habit to cover himself with, could not fail to have some of the uneasy feelings which must have beset the historical fox when, after leaving the trap, in which his tail remained, he presented himself to his normally elongated companions. So I took thought, and invented what I conceived to be the appropriate title of agnostic. It came into my head as suggestively antithetic to the gnostic of Church history, who professed to know so much about the very things of which I was ignorant; and I took the earliest opportunity of parading it at our Society, to show that I, too, had a tail like the other foxes."

Huxley denied that he was disposed to rank himself either as a fatalist, a materialist, or an atheist. "Not among fatalists, for I take the conception of necessity to have a logical, and not a physical, foundation; not among materialists, for I am utterly incapable of conceiving the existence of matter if there is no mind in which to picture that existence; not among atheists, for the problem of the ultimate cause of existence is one which seems to me to be hopelessly out of reach of my poor powers."

The late Duke of Argyll, in his interesting work on "The Philosophy of Belief," makes a very curious attack on Huxley's consistency. He observes that scientific writers use "forms of expression as well as individual words, all of which are literally charged with teleological meaning. Men even who would rather avoid such language if they could, but who are intent on giving the most complete and expressive description they can of the natural facts before them, find it wholly impossible to discharge this duty by any other means. Let us take as an example the work of describing organic structures in the science of biology. The standard treatise of Huxley on the 'Elements of Comparative Anatomy,' affords a remarkable example of this necessity, and of its results. . . .

"How unreasonable it is to set aside, or to explain away, the full meaning of such words as 'apparatuses' and 'plans,' comes out strongly when we analyse the preconceived assumptions which are supposed to be incompatible with the admission of it. . . .

"To continue the use of words because we are conscious that we cannot do without them, and then to regret or neglect any of their implications, is the highest crime we can commit against the only faculties which enable us to grasp the realities of the world." Is not this, however, to fall into the error of some Greek philosophers, and to regard language, not only as a means of communication, but as an instrument of research. We all speak of sunrise and sunset, but it is no proof that the sun goes round the earth. The Duke himself says elsewhere:—

"We speak of time as if it were an active agent in doing this, that and the other. Yet we are quite conscious, when we choose to think of it, that when we speak of time in this sense, we are really thinking and speaking, not of time itself, but of the various physical forces which operate slowly and continuously in, or during, time. Apart from these forces, time does nothing."

This is, it seems to me, a complete reply to his own attack on Huxley's supposed inconsistency.

Theologians often seem to speak as if it were possible to believe something which one cannot understand, as if the belief were a matter of will, that there was some merit in believing what you cannot prove, and that if a statement of fact is put before you, you must either believe or disbelieve it. Huxley, on the other hand, like most men of science, demanded clear proof, or what seemed to him clear proof, before he accepted any conclusion; he would, I believe, have admitted that you might accept a statement which you could not explain, but would have maintained that it was impossible to believe what you did not understand; that in such a case the word "belief" was an unfortunate misnomer; that it was wrong, and not right, to profess to believe anything for which you knew that there was no sufficient evidence, and that if it is proved you cannot help believing it; that as regards many matters the true position was not one either of belief or of disbelief, but of suspense.

In science we know that though the edifice of fact is enormous, the fundamental problems are still beyond our grasp, and we must be content to suspend our judgment, to adopt, in fact, the Scotch verdict of "not proven," so unfortunately ignored in our law as in our theology.

Faith is a matter more of deeds, not of words, as St. Paul shows in the Epistle to the Hebrews. If you do not act on what you profess to believe, you do not really and in truth believe it. May I give an instance? The Fijians really believed in a future life, according to their creed, you rose in the next world exactly as you died here—young if you were young, old if you were old, strong if you were strong, deaf if you were deaf, and so on. Consequently it was important to die in the full possession of one's faculties, before the muscles had begun to lose their strength, the eye to grow dim, or the ear to wax hard of hearing. On this they acted. Every one had himself killed in the prime of life; and Captain Wilkes mentions that in one large town there was not a single person over forty years of age.

That I call faith. That is a real belief in a future life.

Huxley's views are indicated in the three touching lines by Mrs. Huxley, which are inscribed on his tombstone:—

Be not afraid, ye wailing hearts that weep,
For still He giveth His beloved sleep,
And if an endless sleep He wills—so best.

That may be called unbelief, or a suspension of judgment. Huxley doubted.

But disbelief is that of those who, no matter what they say, act as if there was no future life, as if this world was everything, and in the words of Baxter in "The Saints' Everlasting Rest," profess to believe in Heaven, and yet act as if it was to be "tolerated indeed rather than the flames of Hell, but not to be desired before the felicity of Earth."

Huxley was, indeed, by no means without definite beliefs. "I am," he said, "no optimist, but I have the firmest belief that the Divine Government (if we may use such a phrase to express the sum of the 'customs of matter') is wholly just. The more I know intimately of the lives of other men (to say nothing of my own), the more obvious it is to me that the wicked does not flourish nor is the righteous punished."

One of the great problems of the future is to clear away the cobwebs which the early and mediæval ecclesiastics, unavoidably ignorant of science, and with ideas of the world now known to be fundamentally erroneous, have spun round the teachings of Christ; and in this Huxley rendered good service. For instance, all over the world in early days lunatics were supposed to be possessed by evil spirits. That was the universal belief of the Jews, as of other nations, 2000 years ago, and one of Huxley's most remarkable controversies was with Mr. Gladstone and Dr. Wace with reference to the "man possessed with devils," which, we are told, were cast out and permitted to enter into a herd of swine. Some people thought that these three distinguished men might have occupied their time better than, as was said at the time, "in fighting over the Gaderene swine." But as Huxley observed:—

"The real issue is whether the men of the nineteenth century are to adopt the demonology of the men of the first century as divinely-revealed truth, or to reject it as degrading falsity."

And as the first duty of religion is to form the highest conception possible to the human mind of the Divine Nature, Huxley naturally considered that when a Prime Minister and a Doctor of Divinity propound views showing so much ignorance of medical science, and so low a view of the Deity, it was time that a protest was made in the name, not only of science, but of religion.

Theologians themselves, indeed, admit the mystery of existence. "The wonderful world," says Canon Liddon, "in which we now pass this stage of our existence, whether the higher world

of faith be open to our gaze or not, is a very temple of many and august mysteries. . . . Everywhere around you are evidences of the existence and movement of a mysterious power which you can neither see, nor touch, nor define, nor measure, nor understand."

One of Huxley's difficulties he has stated in the following words: "Infinite benevolence need not have invented pain and sorrow at all—infinite malevolence would very easily have deprived us of the large measure of content and happiness that falls to our lot."

This does not, I confess, strike one as conclusive. It seems an answer—if not perhaps quite complete, that if we are to have any freedom and responsibility, the possibility of evil follows necessarily. If two courses are open to us, there are two alternatives; either the results are the same in either case, and then it does not matter what we do; or the one course must be wise and the other unwise. Huxley, indeed, said in another place:—"I protest that if some great power could agree to make me always think what is true, and do what is right, on condition of being turned into a sort of clock and wound up every morning before I got out of bed, I should instantly close with the offer. The only freedom I care about is the freedom to do right; the freedom to do wrong I am ready to part with on the cheapest terms to any one who will take it of me. But when the Materialists stray beyond the borders of their path, and talk about there being nothing else in the world but Matter and Forces and necessary laws, ... I decline to follow them."

Huxley was no enemy to the existence of an Established Church.

"I could conceive," he said, "the existence of an Established Church which should be a blessing to the community. A church in which, week by week, services should be devoted, not to the iteration of abstract propositions in theology, but to the setting before men's minds of an ideal of true, just and pure living; a place in which those who are weary of the burden of daily cares should find a moment's rest in the contemplation of the higher life which is possible for all, though attained by so few; a place in which the man of strife and of business should have time to think how small, after all, are the rewards he covets compared with peace and charity. Depend upon it, if such a Church existed, no one would seek to disestablish it."

It seems to me that he has here very nearly described the Church of Stanley, of Jowett, and of Kingsley.

Sir W. Flower justly observed that while "if the term 'religious' be limited to acceptance of the formularies of one of the current creeds of the world, it cannot be applied to Huxley; but no one could be intimate with him without feeling that he possessed a deep reverence for 'whatsoever things are true, whatsoever things are honest, whatsoever things are just, whatsoever things are pure, whatsoever things are lovely, whatsoever things are of good report,' and an abhorrence of all that is the reverse of these; and that, although he found difficulty in expressing it in definite words, he had a pervading sense of adoration of the infinite, very much akin to the highest religion."

Lord Shaftesbury records that "Prof. Huxley has this definition of morality and religion:—'Teach a child what is wise, that is morality. Teach him what is wise and beautiful, that is religion!' Let no one henceforth despair of making things clear and of giving explanations!" ("Life and Works," iii. 282).

I doubt, indeed, whether the debt which Religion owes to Science has yet been adequately acknowledged.

The real conflict—for conflict there has been and is—is not between Science and Religion, but between Science and Superstition. A disbelief in the goodness of God led to all the horrors of the Inquisition. Throughout the Middle Ages and down almost to our own times, as Lecky has so powerfully shown, the dread of witchcraft hung like a black pall over Christianity. Even so great and good a man as Wesley believed in it. It is Science which has cleared away these dark clouds, and we can hardly fail to see that it is just in those countries where Science is most backward that Religion is less well understood, and in those where Science is most advanced that Religion is purest. The services which Science has rendered to Religion have not as yet, I think, received the recognition they deserve.

Many of us may think that Huxley carried his scepticism too far, that some conclusions which he doubted, if not indeed proved, yet stand on a securer basis than he supposed.

He approached the consideration of these awful problems, however, in no scoffing spirit, but with an earnest desire to arrive at the truth, and I am glad to acknowledge that this has been generously recognised by his opponents.

From his own point of view, Huxley was no opponent of religion, however fundamentally he might differ from the majority of clergymen. In Science we differ, but we are all seeking for truth, and we do not dream that any one is an enemy to "science."

In Theology, however, unfortunately as we think, a different standard has been adopted. Theologians often, though no doubt there are many exceptions, regard a difference from themselves as an attack on religion, a suspension of judgment as an adverse verdict, and doubt as infidelity.

It is therefore only just to them to say that their obituary notices of Huxley were fair and even generous. When they treated him as a foe they did so, as a rule, in a spirit as honourable to them as it was to him.

The *Christian World*, in a very interesting obituary notice, truly observed that "if in Huxley's earlier years the average opinion of the churches had been as ready as it is now to accept the evolution of the Bible, it would not have been so startled by Darwin's theory of the evolution of man; and Darwin's greatest disciple would have enjoyed thirty years ago the respect and confidence and affection with which we came to regard him before we lost him."

"Surely it is a striking and suggestive fact that both the retiring and the incoming President of the Royal Society, by way of climax to their eulogies, dwelt on the religious side of Huxley's character. "If religion means strenuousness in doing right, and trying to do right, who," asked Lord Kelvin, "has earned the title of a religious man better than Huxley?" And similarly Sir J. Lister, in emphasising Huxley's intellectual honesty, "his perfect truthfulness, his whole-hearted benevolence," felt impelled to adopt Lord Kelvin's word and celebrate "the religion that consists in the strenuous endeavour to be and do what is right."

Huxley was not only a great man, but a good and a brave one. It required much courage to profess his opinions, and if he had consulted only his own interests he would not have done so, but we owe much to him for the inestimable freedom which we now enjoy.

When he was moved to wrath it was when he thought wrong was being done, the people were being misled, or truth was being unfairly attacked, as, for instance, in the celebrated discussion at Oxford. The statue in the Natural History Museum is very powerful and a very exact likeness, but it is like him when he was moved to righteous indignation. It is not Huxley as he was generally, as he was when he was teaching, or when in the company of friends. He was one of the most warm-hearted and genial of men. Mr. Hutton, who sat with him on the Vivisection Commission, has recorded that "considering he represented the physiologists on this Commission, I was much struck with his evident horror of anything like torture even for scientific ends." I do not, however, see why this should have surprised him, because the position of physiologists is that it is the anti-vivisectionists who would enormously increase the suffering in the world. To speak of inflicting pain "for scientific ends" is misleading. It is not for the mere acquisition of useless knowledge, but for the diminution of suffering and because one experiment may prevent thousands of mistakes and save hundreds of lives. The medical profession may be mistaken in this, but it is obvious that their conviction, whether it be right or whether it be wrong, is not only compatible with, but is inspired by, a horror of unnecessary suffering.

The great object of his labours was, in his own words, "to promote the increase of natural knowledge and to forward the application of scientific methods of investigation to all the problems of life." His family life was thoroughly happy. He was devoted to his children, and they to him. "The love our children show us," he said in one of his letters, "warms our old age better than the sun."

Nor can I conclude without saying a word about Mrs. Huxley, of whom her son justly says that she was "his help and stay for forty years, in his struggles ready to counsel, in adversity to comfort; the critic whose judgment he valued above almost any, and whose praise he cared most to win; his first care and his latest thought, the other self, whose union with him was a supreme example of mutual sincerity and devotion."

At a time of deep depression and when his prospects looked most gloomy he mentions a letter from Miss Heathorn as

having given him "more comfort than anything for a long while. I wish to Heaven," he says, "it had reached me six months ago. It would have saved me a world of pain and error."

Huxley had two great objects in life as he has himself told us. "There are," he said, "two things I really care about—one is the progress of scientific thought, and the other is the bettering of the condition of the masses of the people by bettering them in the way of lifting themselves out of the misery which has hitherto been the lot of the majority of them. Posthumous fame is not particularly attractive to me, but, if I am to be remembered at all, I would rather it should be as 'a man who did his best to help the people' than by any other title."

It is not only because we, many of us, loved him as a friend, not only because we all of us recognise him as a great naturalist, but also because he was a great example to us all, a man who did his best to benefit the people, that we are here to do honour to his memory to-day.

THE ORIGIN AND PROGRESS OF SCIENTIFIC SOCIETIES.[1]

ON the present occasion I propose to say a few words on a subject of little practical importance, so far as the needs of every-day life are concerned, but still not without some general interest, and not without a direct bearing on the history of the advancement of human knowledge—the "Origin, Development and Aims of our Scientific Societies." The subject is a large one, and it will be impossible to enter into details with regard to its almost innumerable ramifications. In justification of a considerable degree of limitation, I may incidentally mention that the "Official Year-book of the Scientific and Learned Societies of Great Britain and Ireland," for the year 1900, extends over upwards of 290 octavo pages.

In England no learned society received a Royal Charter before 1662, when the Royal Society was incorporated by Charles II. It had, however, been instituted in 1660. So early, moreover, as 1645 the lovers of experimental philosophy formed a society which met weekly in London on a certain day to treat and discourse of philosophical affairs, and many of its members became subsequently the first Fellows of the Royal Society. About the year 1648–1649, this little band of students was divided into two—one part remaining in London and the other migrating to Oxford, where a Philosophical Society of Oxford was established that subsequently for some time worked in concert with the Royal Society, and did not finally cease to exist until 1690.

About the year 1572, "divers gentlemen of London, studious in antiquities, formed themselves into a College or Society of Antiquaries." The honour of this foundation is "entirely due to that munificent patron of letters and learned men, Archbishop Parker. The members met near 20 years at the house of Sir Robert Cotton, and, in 1589, resolved to apply to the Queen for a charter of incorporation, and for some public building, where they might assemble and have a library." A petition was prepared for presentation to Her Majesty Queen Elizabeth praying for the incorporation of "An Academy for the Studye of Antiquity and History," the meetings of which were to be held in the Savoy, or the dissolved Priory of St. John of Jerusalem, or elsewhere. It is uncertain whether this petition was ever presented, but the Queen seems to have given the society her countenance, and under the presidency of Archbishops Parker and Whitgift successively it flourished, and a list of thirty-eight of its members, comprising such well-known names as Camden, Cotton, Erdeswicke, Lambarde, and Stow, is still extant. For some cause or other Elizabeth's successor, James I., thought fit to dissolve the society in 1604, and though attempts were made to revive it in 1617, and though there was an Antiquaries' feast on July 2, 1659, the society remained in a dormant condition until 1707. It then held weekly meetings at the "Bear Tavern" in the Strand, and afterwards at the "Young Devil Tavern" in Fleet Street, subsequently moving to the "Fountain Tavern." In 1718 the society was reconstituted, and in 1751 a Charter of Incorporation was granted to it by George II., who declared himself the founder and patron of the Society of Antiquaries of London.

Having traced the inception of the two oldest of our learned societies, which in their early stages partook more of the nature of clubs than of what are now known as societies, I propose, before considering their further developments, to say something as to the proper aims and objects of a learned society, and the means usually adopted for carrying them into effect. Such a society is an association of persons united together by common tastes and anxious to improve or extend some particular branch of knowledge, or even the whole range of scientific inquiry. With this object in view it becomes necessary to hold periodical meetings for the discussion of subjects in which the society is interested, and for taking such action in respect of them as may seem desirable. The holding of such meetings involves an organisation and the appointment of presidents to take the chair at meetings, of secretaries to summon them, and of a treasurer to receive those subscriptions without which an association of the kind cannot exist. Moreover, for the determination of questions of policy and finance, especially when the society issued publications, a council of some kind becomes a necessity. It is on this organisation that the success or failure of a society mainly depends, and the questions as to the length of period that presidents and others should remain in office, what proportion of new blood should be infused into the council each year, and how far those in power are carrying out the views of the bulk of the members of the society, have frequently been discussed with more or less warmth. In some instances the too conservative apathy of the council has led to disruption and the foundation of new societies, or to the society under their charge being reduced to a state of inanimate slumber, while on the other hand too rapid revolutionary measures have led to diminutions in numbers, if not to absolute rebellion. Much, of course, of the welfare of a society depends upon the character of its publications being kept at a high level, and on their being brought out with scrupulous regularity.

There is one condition in the life of a scientific society which is entirely beyond its control or that of its council, and this condition may be superinduced by the activity of the society itself. As researches proceed and knowledge extends, new branches of inquiry are opened, which can only be investigated by those who apply themselves specially to the subject. New publications are required, particular days have to be set apart for the discussion of the new subject, and eventually it is found desirable to establish a separate branch of the old society, or to constitute a new one. The latter course is the one that has been most often adopted, especially in the case of biological science; and not infrequently the new society finds a home in the apartments of the parent society, and under its fostering care.

Let us now go back to the period when Charles II. granted his second Charter to the Royal Society of London for improving natural knowledge. The Society of Antiquaries was in abeyance, so that the Royal Society was practically the only institution of the kind in Britain, and its aims were naturally wide. On November 20, 1663, the society consisted of 131 Fellows, of whom 18 were noblemen, 22 baronets and knights, 47 esquires, 32 doctors, 2 bachelors of divinity, 2 masters of arts, and 8 strangers or foreign members. With the exception of the large proportion of physicians or doctors, it will be observed that the society in the main was composed of noblemen and gentlemen of independent position, and that the professional element was to a very great extent wanting. Great attention was paid to experimental methods; but "what the learned and inquisitive are doing, or have done in physick, mechanicks, opticks, astronomy, medicine, chymistry, anatomy, both abroad and at home" were subjects on which they were solicitous. Many of the branches of science diligently pursued at the present day were either unknown or in their infancy. The variation of the compass had been observed, but magnetism and electricity presented almost untrodden fields; the steam engine was in an embryonic stage; visions of space with four or more dimensions had not visited the poetical mathematical brain; microscopes and telescopes were in their infancy; the family of the planets was no more numerous than of old; the circulation of the blood had not met with universal acceptance, and the existence of *bacilli* was but dimly conceived; chemistry was of the crudest, and the elements were earth, air, fire and water; anatomy had already made notable advances, but Dermatological, Laryngological, and Odontological societies were not even dreamt of; geology was unborn, and palæontology did not exist, except in connection with Noah's Deluge.

One of the results of this very wide scope of the Royal Society was, that at its meeting the variety of subjects brought forward

[1] Abridgment of an address delivered at the opening meeting of the Society of Arts, November 21, by Sir John Evans, K.C.B., F.R.S.

for discussion was great; and the early volumes of the *Philosophical Transactions* contain a large amount of miscellaneous reading. I am not sure that, as a means of whiling away a spare half-hour, one of the first twenty volumes of the *Transactions* would not by most persons be found more attractive and amusing than the volume, say, of Series A for the year 1900.

The Society for the Encouragement of Arts, Manufactures, and Commerce was founded in 1754, but not incorporated until 1847, and this society, together with the two already mentioned, form the trio from which nearly all the numerous learned societies of the present day have sprung, by what may be regarded as a natural process of evolution.

As might have been expected, Scotland was not long in following the example set by England, and the Medical Society of Edinburgh was instituted in 1734, to be followed by the somewhat kindred Harveian Society in 1752. In the meantime, the Royal Society of Edinburgh, or, as it was originally called, the Philosophical Society, was established in 1739. The "Royal Physical Society of Edinburgh," exclusively devoted to "Natural History and the Physical Sciences," was founded in 1771, and by 1813 had absorbed no less than six other societies, which became incorporated in it.

In Ireland, the Royal Irish Academy for "the study of Science, Polite Literature, and Antiquities," was founded in 1785, and may be regarded as combining the attributes of the three parent societies in London.

Among the off-shoots of the Royal Society of London, the first perhaps is the Medical Society, founded in 1773. The Linnean Society, for the cultivation of natural history in all its branches, was founded in 1788, and has from 700 to 800 Fellows. These are the only two London societies coming under this category that date from the last century.

During the century now drawing to its close the vast advances in science, and the innumerable aspects it assumes, has led to the foundation of numerous scientific societies, each with a more or less limited scope. In natural history we have the Horticultural (1804), the Zoological (1826), the Entomological (1833), the Ornithological (1837), the Royal Botanic (1839), the Ray Society (1844), the Palæontographical (1847), and others that it would be tedious to mention.

Geology as a new science had a society founded for its study in 1807, the Geologists' Association followed in 1858, and at a later date the Mineralogical Society (1876). The Royal Astronomical Society (1820) has been supplemented by the British Astronomical Association. Mathematics and Physics have also their own societies, as have also Statistics, a subject which has a mathematical side as well as one in the direction of commerce and the affairs of ordinary life. Engineering is represented, not only by the Institution of Civil Engineers (1818), but by the Institution of Mechanical Engineers (1847), of Mining Engineers (1851), the Iron and Steel Institute (1869), and that of Electrical Engineers (1871). Geography has had its own Royal Society since 1830, Microscopy its society since 1839, and Meteorology since 1850. For medicine, pharmaceutics, pathology, neurology, anatomy, and some other branches of medical inquiry, special societies have been founded in London. The Victoria Institute or Philosophical Society of Great Britain was founded in 1865, its primary object being the attempt to reconcile apparent discrepancies between Christianity and science.

In Edinburgh and Dublin scientific societies have multiplied, though not to a similar extent; and throughout the United Kingdom there are numerous literary and philosophical societies, that of Manchester dating back to 1781. There are also several provincial geological societies, and almost every county has its natural history society or club.

Moreover, the British Association for the Advancement of Science, founded in 1831, continues to hold its annual meetings at different centres in the Empire, and helps to maintain the general interest in the advancement of knowledge and to kindle or keep alive local zeal.

The offshoots from the Society of Antiquaries have not been so numerous or important as those from the Royal Society, the field of Archæology being much more restricted than the wide domain of more purely "natural knowledge." The Society of Antiquaries of Scotland dates, however, from 1780, and that of Newcastle-on-Tyne from 1813, while the Literary and Antiquarian Society of Perth goes back to 1784. Several branches of antiquarian study have now their own societies. The Numismatic Society was founded in 1836, the Royal Historical Society in 1868, the Society of Biblical Archæology in 1871, the Palæontographical in 1873, and that for Hellenic studies in 1879. There are also special societies for the exploration of Palestine and Egypt, as well as the important Royal Asiatic Society with its different branches. The peripatetic habits of the Royal Archæological Institute and of the British Archæological Association (both 1843) help to maintain the warmth of local interest and to disseminate a certain amount of archæological information.

Anthropology and Ethnology have made great advance since the foundation of the Ethnological Society in 1843, and of the Anthropological in 1863. The two merged in 1871 to form the Anthropological Institute, which has rendered signal services to science. A minor branch of anthropology—Folk Lore—has had its own society at work since 1878.

The Society of Arts—to make use of its shortened title—can claim nearly as numerous an offspring as its elder sisters the Royal Society and the Society of Antiquaries. Her descendants, moreover, are fairly entitled to as high, if not indeed a higher, rank and importance. It is not merely the Royal Scottish Society of Arts (1821) that she can claim as an offshoot, but it was the Society of Arts that first in England devoted attention to the all-important objects of forestry and agriculture. The Royal Agricultural Society originated not earlier than 1838, though in Scotland a Society of Improvers of Agriculture was instituted in 1723, a Dublin Agricultural Society in 1731, the Bath and West of England Society in 1777, and the Highland Society in 1784.

It would, moreover, be unfair not to credit the Society of Arts as well as the Royal Society with having laid the foundations on which the Institution of Civil Engineers and the cognate bodies have been erected. The Chemical Society was established at a meeting held at the rooms of the Society of Arts in 1841. From this arose the Institute of Chemistry in 1877. The Society of Chemical Industry (1881) to a large extent grew out of the Chemical Section of the Society of Arts, which dealt for some years with the chemical industries, and was dropped on the foundation of the society. The Sanitary Institute and the other sanitary societies certainly owe their origin to the Conferences on the Health and Sewage of Towns held by the Society of Arts in 1877, 1879, and 1880. The City and Guilds' Institute also originated in consequence of the action of the society in the matter of technical education. They took up and carried on the technological examination founded by the Society of Arts.

It must never be forgotten that in its earlier days inventions of all useful kinds, and all that was new in machinery and manufactures, came within the scope of the society, which in thirty years spent many thousands of pounds in rewards and premiums for useful inventions.

It took a very active part in all educational movements and a warm interest in the welfare of our Colonies, and to its credit be it said that the examinations of the Society of Arts still rank among the most useful and thorough, while the existence of our Indian Section still evinces our interest in the prosperity of the dependencies of the Empire.

What the society has done for the advancement of art, it is difficult for us of the present day fully to appreciate; but it must be remembered that one of the first, if not, indeed, the first public exhibition of pictures was that held in the society's rooms in 1760, and that from this exhibition sprang the Royal Academy, the first exhibition of which, comprising one hundred and thirty-six works only, was opened in 1769. We may, therefore, here claim the Royal Academy as in a certain sense an offshoot from our body. The Royal Institute of British Architects, founded in 1835, may also in some degree be regarded as connected with the Royal Academy, which admits architects among its members. The Photographic Society also grew out of an exhibition of photographs, the first of the kind held in our rooms. The foundation of the Royal College of Music is likewise due to the exertions of the Society of Arts.

It would indeed be difficult to say how far the work done by any society would have been accomplished by the individuals composing that society, without combination or collective organisation. A society of course is only a collection of individuals, and the work of the society is the work of the individuals composing it.

A society offers opportunities for discussion, brings men of similar ideas together, and substitutes collective and organised action for isolated individual effort. It affords means of publication, organises research, records discoveries, stimulates

invention, and assists students by providing a common meeting-place and centre of action. Every scientific discoverer desires immediate publication of his work, both for his own reputation and to secure the assistance of his colleagues. Every industrial inventor requires publication in order that he may secure the natural profits of his invention. A society systematises and arranges the science or study which is its subject-matter.

The present condition of science is certainly due to the organised efforts of such societies as the Royal Society and its subordinate societies in this and other countries. They secure public recognition for science and those who pursue it; they prevent overlapping; serve to deter different men from working on the same lines; and they bring influence to bear on the public and on the Government. Any individual is less powerful by himself than when he is associated with others seeking the same object. An active society is a corporation with a perpetual succession, and it never dies. The work carried on by an isolated student ceases at his death, but the work done by a number of students associated together goes on and on. As one man drops out, another takes his place.

An excellent example of the reciprocal influence of scientific workers and of a scientific institution upon each other is afforded by the Royal Institution. Without Davy, Faraday, or Tyndall, the Royal Institution would never have become the important body it now is. But without the Royal Institution neither Davy nor Faraday would have had any opportunity for carrying out their scientific work and of obtaining their scientific reputation, and perhaps the same may be said to a certain extent of Dr. Tyndall.

The history that I have been tracing comprises within it a record of the advance in many directions of our acquaintance with the secrets of nature, of our turning that acquaintance to practical account, and of the consequent progress of the nation in material prosperity. It bears witness likewise to that specialisation in science, which, though by no means an unmixed blessing, seems to be of necessity associated with all advancement in natural knowledge. The days are long since past when any single individual could attempt to cope with the whole encyclopædia of science, but the question not unfrequently arises at the present day whether the position of the specialist would not be more secure were the foundations on which he builds extended over a larger area, and were his scientific sympathies somewhat wider in their character.

Another question that may be asked is whether there is any need for this multiplicity of societies. The answer from any one who in whatever manner believes in evolution will be, that at the time of founding each society a necessity for it must at all events have been thought to exist, and that the analogous societies at that time in being must have been either unable or unwilling to adjust or expand themselves so as to include the subject for the study of which the new society was instituted. Many of the subjects, for instance, that originally came within the domain of the Royal Society, and indeed are still included within it, have by degrees been not absolutely banished from it, but relegated in the main to other societies, founded more especially for the study and illustration of such subjects. The Linnean, the Astronomical, the Chemical, and the Geological Societies afford instances in point, and any attempt to suppress such societies, and to bring their members all within the fold of the Royal Society, would have a disastrous effect on the advance of science, and would absolutely overweight the powers of the Royal Society itself. At the same time it must be remembered that accounts of important discoveries in any of these branches of knowledge are cordially welcomed by the Royal Society, and that it is usually the case that the leading Fellows of these special societies are also Fellows of the Royal Society. The same in a lesser degree holds good with the Society of Antiquaries, as archæological discoveries, especially when bearing on the early history of man, are welcomed alike on both sides of the quadrangle at Burlington House.

Turning to the more purely philosophical societies that have been established in London, it would seem as if for some reason or other the soil was not congenial for their growth or longevity. The Dialectical Society, founded in 1865, was dissolved in 1888; the Psychological, founded in 1875, ceased to exist in 1879, but was resuscitated under the name of the Society for Psychical Research in 1882. The Zetetical Society, established in 1878, and the Aristotelian in 1880, do not appear in Whitaker's List of Societies and Institutions, though the latter, notwithstanding that its members are few, is still in active operation. Altogether the number of those interested in abstract philosophy seems to bear no proportion to that of the votaries of the study of nature in all its phases and of those who devote themselves to the application of science to the good of mankind.

In the Institut de France, one of the Académies is that of Sciences Morales et Politiques, which, however, is divided into five sections. Of the eight places devoted to philosophy, only six were filled at the beginning of the present year, but this may have been purely accidental. The mention of the Institut suggests the question how far a similar association of academies would meet the requirements of this country. Such a question is beyond the limits of the present address, but in passing I may say that the necessary limitations of the Institut, the payment for attendance, the method of election of its members, and its close connection with the Government of the day, all present features which are hardly in accordance with our insular traditions. In Paris itself the Institut has had to be supplemented by various important scientific societies, such, for instance, as the Geological Society and the Society of Antiquaries of France.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Dr. S. H. Hodgson has been appointed an elector to the White's professorship of moral philosophy in succession to the late Prof. Henry Sidgwick.

It will shortly be proposed in Convocation to confer the degree of D.Sc., *honoris causa*, upon Dr. Oliver J. Lodge, principal of the University of Birmingham.

Science scholarships are announced for competition on December 4 at Balliol College, Trinity College and Christchurch; on December 11 at Magdalen College; on January 15 at Jesus College.

CAMBRIDGE.—The complete degree of M.A., *honoris causa*, is to be conferred on Mr. G. H. F. Nuttall, M.D. California, Ph.D. Göttingen, University lecturer in bacteriology and preventive medicine, and on Mr. T. Strangeways Pigg, Advanced Student of St. John's College, University demonstrator of pathology.

The Special Board for Medicine propose a new scheme for the degrees of M.B. and B.C., whereby candidates shall be required to pass a suitable examination in pharmacology (*i.e.* the physiological actions of remedies), and in general pathology and the elements of hygiene, before admission to the final or qualifying examination in medicine, surgery and midwifery.

THE new Ravenscroft metallurgical laboratory of the Birkbeck Institution will be opened on Saturday next, December 1.

DR. BRILLOUIN has been nominated to succeed the late Prof. Bertrand as professor of general and mathematical physics at the Collège de France.

DR. THOMAS BUZZARD, a Fellow and member of the Council of King's College, London, has been appointed one of the representatives of the college upon the Senate of the University of London, in succession to Lord Lister, who has resigned.

AT a meeting of the associates of the Owens College, Manchester, held on November 21, Prof. J. J. Thomson, F.R.S., who is himself an associate, was elected a representative of the associates on the Court of Governors of the college for a period of five years.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, August 21.—"Note on the Occurrence of a Seed-like Fructification in certain Palæozoic Lycopods." By D. H. Scott, M.A., Ph.D., F.R.S.

The specimens described in the present note show that seed-like bodies, identical with those figured by Williamson under the name of *Cardiocarpon anomalum*, were borne on Lepidodendroid cones, otherwise indistinguishable from *Lepidostrobus*. They thus prove that under the genus *Cardiocarpon*, and even under the "species" *C. anomalum*, totally different objects have been confounded, namely, the seeds of Cordaiteæ or Cycads

on the one hand, and the integumented megasporangia of certain Palæozoic Lycopods on the other. The latter organs present close analogies with true seeds, but are wholly distinct in detailed structure from the Gymnospermous seeds above mentioned. The discovery of the specimens of the new cone is due to Messrs. J. Lomax and G. Wild, who recognised it as a *Cardiocarpon*-bearing strobilus, resembling a *Lepidostrobus*. The original specimens, which are calcified and generally well preserved, were derived from the Ganister beds of the Lower Coal-measures of Lancashire. A closely similar fructification occurs, at a much lower horizon, in the Burntisland beds of the Calciferous Sandstone Series.

The strobilus is of the ordinary *Lepidostrobus* type. The cylindrical axis bears numerous spirally disposed sporophylls, each of which consists of a long horizontal pedicel, expanding at the distal end into a rather thick lamina, which turns vertically upwards. Anatomically, the structure is also that of a *Lepidostrobus*. The ligule is sometimes well preserved; it is seated in a depression of the upper surface of the sporophyll, at the distal end of the sporangium, and is thus in the normal position.

With one exception, the specimens of the strobilus are immature, and their tissues not quite fully differentiated. These younger specimens bear sporangia which are essentially those of a *Lepidostrobus*. A single large sporangium is seated on the upper surface of the horizontal pedicel of each sporophyll, to the median line of which it is attached along almost its whole length. The sporangial wall has the structure characteristic of *Lepidostrobus*. Within the sporangial cavity, the membranes of the megaspores are usually preserved; a single large megaspore almost fills the sporangium, but smaller, abortive spores, with thicker walls, are also present. It appears that a single tetrad was developed in each megasporangium, and that of the four sister-cells one only came to perfection, constituting the functional megaspore.

In one specimen, discovered by Mr. Wild, the strobilus is in a more advanced condition. In its upper part the sporophylls simply bear sporangia, as above described, but lower down in the cone these are replaced by integumented, seed-like structures, identical with the detached bodies called *Cardiocarpon anomalum* by Williamson. Mr. Wild's specimen, then, demonstrates that the *Cardiocarpon anomalum* of Williamson was borne on a cone with all the characters of a *Lepidostrobus*, and that it represents the matured condition of the megasporangium and sporophyll.

The detailed comparison of specimens in the young and the mature condition has shown the nature of the change, which converts the megasporangium, together with its sporophyll, into a seed-like organ. A thick integument has grown up from the sporophyll, completely overarching the megasporangium, except for a narrow crevice left open at the top. When seen in a section tangential to the strobilus as a whole, this crevice is cut across, and presents exactly the appearance of a micropyle; in reality it differs from a micropyle in being a narrow slit, extending almost the whole length of the sporangium, in the radial direction, whereas the micropyle of an ordinary seed is a more or less tubular passage.

In a strobilus associated with the seed-like specimens, and probably of the same species, but bearing microsporangia, it was found that the latter, like the megasporangia of the female cone, are provided with integuments.

The Burntisland specimens, which from their horizon are presumably of a distinct species, are of interest for two reasons: in one specimen the ligule is clearly shown, enclosed by the integument, the only example of this organ so far observed in the mature, seed-like stage of the fructification. Another of the Burntisland specimens was the first observed in which the prothallus was present. It fills a great part of the functional megaspore, which is almost co-extensive with the sporangial cavity, and consists of a large-celled tissue, resembling the prothallus of *Isoetes* or *Selaginella*. The peripheral prothallial cells are smaller than the rest, but no archegonia could be detected. [In a section, since examined, cut by Mr. Lomax from one of the Coal-measure specimens, the prothallus is even better preserved. October 9, 1900.]

The bodies described in this note resemble true seeds in the possession of a testa or integument, and in the fact that one megaspore or embryo-sac alone came to perfection; the seed-like organ was likewise shed entire, and appears to have been indehiscent. In many points of detail, however, the reproductive bodies in question differ from the seeds of any known Gymnosperms; they afford no proof of the origin of the latter class from the Lycopods. The newly-discovered fructification nevertheless shows that certain Palæozoic Lycopods crossed the boundary line which we are accustomed to draw between Sporophyta and Spermophyta. As these fossils appear worthy of generic rank, it is proposed to found the genus *Lepidocarpon* for their reception.

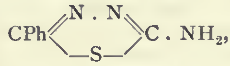
Physical Society, November 23.—Prof. Everett, F.R.S., Vice-President, in the chair.—A paper on a self-adjusting Wheatstone's Bridge, by E. H. Griffiths and W. C. D. Whetham, was read by Mr. Whetham. The object of this paper is to describe a cheap and easy method of getting a self-adjusting bridge to show on a scale the actual resistance of any wire. Contact with the bridge wire is made by means of a light horozontal bar, which is suspended by a phosphor-bronze strip from the coil of the d'Arsonval galvonometer used with the instrument. A second bar, parallel to and above the first, is rigidly connected with the coil. A wooden beam, worked by clockwork, moves up and down between the bars and clamps them alternately. When the beam is down contact is made with the bridge wire. If this contact is not at the zero point a current will flow through the coil, and if the cell is connected up the proper way, it will turn the coil so as to bring the upper bar nearer to the null point. This puts a twist into the phosphor-bronze strip, and when the beam rises and clamps the upper bar the torsion comes into play, and brings the lower bar under the upper one. The beam then descends and makes contact at this point, and if any current flows through the galvanometer there is further movement until the null point is reached. Any alteration in the resistance of the wire under experiment causes a movement of the zero point on the bridge wire, and this is followed by the lower arm. The position of the lower arm can be directly indicated by means of a scale. Prof. S. P. Thompson asked how the scale was calibrated. Mr. Whetham said the scale was arbitrary, but it could be calibrated by the known resistance of the bridge wire per unit length. Extension of the range can be obtained by shunting the bridge wire with various resistances. Mr. Glazebrook asked how sensitive the bridge was. Mr. Whetham said that working with a dry cell it could easily indicate one degree on a platinum thermometer. Mr. Blakesley pointed out that if the cell was connected up the wrong way the zero point would be an unstable one.—A paper on the liquefaction of hydrogen was read by Dr. M. W. Travers. These experiments were undertaken in order to provide liquid hydrogen in sufficient quantity for the separation of neon from the helium with which it is usually mixed. The separation is effected by cooling the gases to the temperature of hydrogen boiling at atmospheric pressure. The principles and conclusions do not differ from those of Dewar, but as the production of liquid hydrogen is neither difficult nor costly, an account of the experiments is given. In 1884 Wroblewski showed that strongly cooled and compressed hydrogen, on being allowed to expand, formed mist or spray in the tube; and later Olszewski repeated these experiments on a larger scale and determined the temperature of the liquid. Other methods of liquefying hydrogen have been suggested by Lord Rayleigh and Kammerlingh Onnes. In the case of many gases a fall of temperature takes place on free expansion, but under ordinary circumstances the temperature rises in the case of hydrogen and helium. The principle of free expansion was first applied by Hampson and Linde to the liquefaction of air. Within the last two years Dewar has shown that, at a temperature close to $-200°$ C., hydrogen behaves as an imperfect gas and becomes cooled when allowed to expand. This principle has been applied by Dewar to the liquefaction of hydrogen in quantity. In the author's experiments, hydrogen under a pressure of 200 atmospheres passes through a coil which is cooled to $-80°$ C. by a mixture of solid carbonic acid and alcohol. It then enters another coil contained in a chamber which is continually replenished with liquid air. The lower portion of this coil passes into another chamber, which is closed and communicates through a pipe with an exhaust pump. Liquid air flows continuously from the first chamber into the second through a pin valve controlled by a lever. The liquid air, boiling under a pressure of 100 mm. of mercury, lowers the temperature to $-200°$ C. The gas then passes into a regenerator coil, which is enclosed in a vacuum vessel, and expanding at a valve, passes upwards, through the interstices of the coil and the annular space surrounding the chambers through

which the gas first passes, to an outlet whence it can return to the main supply pipe. The liquid which separates from the gas is ultimately collected in a vacuum vessel. The apparatus, with the exception of the compressor, motor and Hampson air liquefier, is comparatively inexpensive. About 50*l.* is required for the additional apparatus, and each time liquid hydrogen is made involves a further expenditure of about a sovereign. Dr. Hampson said he would like to offer a correction. Dr. Travers had said that he (Dr. Hampson) was the first to liquefy air by the application of the counter current process to the Joule-Thomson effect. Although he was the first to make the proposal he was not the first to apply it. He made the proposal to Prof. Dewar's assistant in 1894, and air was liquefied by Prof. Dewar by this method. Dr. Travers had referred at length to a valve which he (Dr. Hampson) had devised, but as it was straightforward common sense he did not wish to accept any credit for the use it had been to the author in his experiments. He would like to call attention to the remarkable features of the work in two respects—the economy of means and the magnitude of results. By means of liquid hydrogen Prof. Ramsay and Dr. Travers had succeeded in obtaining the physical and other properties of some of the rarer gases. Prof. S. P. Thompson said the author had asserted that the Joule-Thomson effect for hydrogen changes in sign at some temperature, and expressed his interest in the fact that it was possible to get a cooling effect by allowing hydrogen to expand. Mr. Boys asked if it was necessary or desirable to allow the hydrogen to expand to atmospheric pressure. Dr. Travers said the mechanical advantages of this were great. Dr. Lehfeldt asked if there had been any attempt to determine the temperature of the liquid, and, secondly, if the apparatus could be employed to determine the magnitude of the Joule-Thomson effect. Dr. Harker asked if the temperature at which the Joule-Thomson effect changes sign was known. Dr. Donnan said that the effect changed sign at the temperature at which "PV" was a minimum. Dr. Travers, in reply to Dr. Lehfeldt, said he had not determined the temperature of the liquid, and the apparatus was not suitable for measuring the Joule-Thomson effect. He should say that the change of sign occurred about $-150°$ C. It was Daniel Berthelot who first pointed out that the change of sign corresponded with the minimum value of "PV," but the experiments of Amagat on the relation between pressure and volume were not sufficiently accurate to fix the temperature.—A paper on the anomalous dispersion of carbon, by Prof. R. W. Wood, was taken as read. Experiments were made with smoke films and with films deposited on plate glass in a vacuum by an incandescent lamp. The dispersion was first measured with a Michelson interferometer, illuminated with monochromatic light of various colours, obtained by prismatic analysis. The fringes were photographed and measured, readings being obtained between wave-lengths ·000040 cm. and ·000066 cm. The results show a steady increase of refractive index from blue to red. The refractive index for sodium light was measured by estimating the thickness of the film and the fringe displacement, and was found to be 2·2. A prismatic deposit of smoke was then made by allowing a piece of plate glass to move uniformly backwards and forwards over the top of a small flame. The deviation produced by this prism was measured by means of a direct vision spectroscope with the prisms removed. Experiments were performed with red and blue light. The mean deviation of red and blue was taken for sodium light, and this result was in good agreement with the deviation obtained by the interferometer method.—A paper on the refraction of sound by wind, by Dr. E. H. Barton, was taken as read. Assuming that the wind is everywhere horizontal, and does not vary in any one horizontal plane, but is different at different levels, then the following results are obtained for rays in the same vertical plane as the wind: (1) The direction of propagation is not usually at right angles to the wave front where there is a wind, consequently the cosecant law for the wave front needs supplementing by another expression giving the direction of the ray. (2) Total reflection cannot occur if the wave front is initially horizontal. (3) In a region where the horizontal wind increases uniformly as we ascend, the rays, instead of forming a catenary, describe a more complicated curve, which, however, reduces to a parabola in the special case of rays whose wave fronts are horizontal. In the paper the relation between direction of propagation and wave front is first worked out and then the refraction of waves and rays on crossing into a new wind zone is considered. This principle is then applied to the diffraction through any number of parallel wind zones, and it is shown that the final inclinations of wave fronts and rays are independent of the characteristic constants of the intermediate zones. It is shown that since a cosecant cannot have a value between $+1$ and -1, total reflexion becomes possible. If, however, the wave front is initially horizontal there is no refraction of the wave front and no total reflexion, but the ray deviates without limit from the vertical, and tends to correspond with the wave front. When reflexion occurs it follows the ordinary optical law. The society then adjourned until December 14, when the meeting will be held at the Royal College of Science, South Kensington.

Chemical Society, November 15.—Prof. Thorpe, President, in the chair.—The following papers were read:—Trichlorobenzoic acid, by F. E. Matthews. Benzonitrile hexachloride is acted upon by alcoholic soda with production of a mixture of trichlorobenzoic acids from which a new trichlorobenzoic acid was isolated; the new acid gives an ester with hydrogen chloride and alcohol and is, therefore, the 1 : 2 : 4-trichloro-3-benzoic acid.—Oxidation of benzalthiosemicarbazone, by G. Young and W. Eyre. Benzalthiosemicarbazone,

$$CHPh : N . N : C(SH) . NH_2,$$

is oxidised to amidophenylthiodiazole,



by ferric chloride. Similar oxidation products are obtained from the 4-substituted methyl and phenyl benzalthiosemicarbazones.—The nitration of benzeneazosalicylic acid, by J. T. Hewitt and J. J. Fox. With dilute nitric acid, benzeneazosalicylic acid yields benzeneazoorthonitrosalicylic acid, whilst with strong nitric acid, paranitrobenzeneazosalicylic acid is obtained.—Upon the collection and examination of the gases produced by bacteria from certain media, by W. C. C. Pakes and W. H. Jollyman. The strictly ærobic organism *Bacillus pyocyaneus* grows in media containing 1 per cent. of potassium or ammonium nitrate under anærobic conditions; the authors conclude that the terms ærobic and anærobic must be extended so as to include the presence of oxygen in the form of nitrates. The gases produced by this organism from nitrated media contain nitrogen and small quantities of oxygen.—The bases contained in Scottish shale oil, by F. C. Garrett and J. A. Smythe. The basic mixture separated from Broxburn shale oil seems to contain no pyridine; α-picoline, $\alpha\gamma\alpha'$-trimethylpyridine, and $\alpha\beta$- and $\alpha\beta'$-dimethylpyridine were isolated from it.—On a simplified method for the spectrographic analysis of minerals, by W. N. Hartley and H. Ramage.

PARIS.

Academy of Sciences, November 19.—M. Maurice Lévy in the chair.—Note on the telescopic planets, by M. de Freycinet. The asteroids studied, 428 in number, appear to belong to eight independent rings, each of which, before breaking up into fragments, turned as one piece round the sun. This hypothesis as to their formation requires three conditions, all of which are shown to be fulfilled.—On the aërostatic observation of the Leonids, by M. J. Janssen. The observations from the balloons ascending from Paris were obscured by clouds, although an altitude of over 13,000 feet was attained. Observations at other stations were also spoiled by the state of the weather.—Sir Joseph Hooker was elected a Foreign Associate in the place of the late Prof. R. Bunsen.—Observations of the Leonid swarm at Meudon, by M. H. Deslandres. Only nine Leonids were seen on the two nights.—On some applications of non-euclidian geometry, by M. Servant.—On the summation of series, by M. Émile Borel.—On a new shadow analyser, by M. J. Macé de Lépinay. The new analyser may be used for any simple rays, and preserves its sensibility in convergent light. By applying a modification of Mouton's method, it is possible to measure easily thicknesses up to several centimetres with an accuracy of $0·14\ \mu$.—On the electrocapillary properties of mixtures and electrocapillary viscosity, by M. Gouy.—The direct combination of nitrogen with the metals of the rare earths, by M. Camille Matignon. A mixture of the oxide of the rare earth with aluminium and magnesium is heated in a tube containing air and connected with a manometer. Under these conditions, with lanthanum, praseodidymium, neodidymium and samarium, the absorption of the oxygen and nitrogen is very rapid; with cerium

and thorium the absorption, although complete, is slower.—Relation between the chemical constitution of the colouring materials derived from triphenylmethane and their absorption spectra in aqueous solution, by M. P. Lemoult. All the dyes examined gave in aqueous solution an absorption spectrum possessing a red luminous band, the centre of which was fixed in position ($\lambda = 6860$).—On blue chlorophylline, by M. M. Tsvett. By a particular mode of treatment, which is described in detail, the author has succeeded in obtaining crystals of a chlorophylline of a pure blue colour, apparently different from the phyllocyanine of Frémy and the chlorophyllines of Sorby and Gautier.—Cryoscopy of human sweat, by M. P. Ardin-Delteil. Normal sweat from a healthy man has an average freezing point of $-0°\cdot24$ C. It may vary in individual cases between $-0°\cdot08$ and $0°\cdot46$ C., the oscillations being in great part due to the variations in the quantity of common salt contained in the perspiration.—On the development of *Sclerostomum equinum*, by M. A. Conté.—On the exosmosis of diastases by plantules, by M. Jules Laurent. Seeds during germination may give out a portion of the diastases necessary to the digestion of their food reserves, and thus utilise certain insoluble organic materials, such as starch, but the phenomenon stops when germination ceases.—Origin of an ochreous clay, characteristic of the red diluvium, by M. Stanislas Meunier.—The uses of transparencies for combining the effects of the synodic revolution with those of terrestrial rotation, by M. A. Poincaré.—Observations on the Leonids at Algiers, by M. H. Tarry.

CAPE TOWN.

South African Philosophical Society, October 3.—T. Stewart, Vice-President, in the chair.—The Secretary communicated a paper by Dr. R. Broom, on *Ictidosuchus primaevus*, *nov. spec.* The paper contained a description of the remains of a small Theriodont reptile from the Karroo Beds of Pearston. The form is specially interesting as illustrating a new Theriodont type, and one which has many affinities with the Dicynodonts.—Prof. J. T. Morrison read a paper on some periodical changes in the rainfall at the Royal Observatory, Cape of Good Hope, since 1841. Prof. Morrison dealt with the records of rainfall that have been kept at the Royal Observatory since the year 1841. These showed certain regularities attended by many apparent irregularities. The author subjected the records to the process of mathematical analysis discovered by Fourier, and so showed evidences of two sets of fluctuations running simultaneously through the monthly amounts of rainfall. These fluctuations completed themselves in approximately nine and ten years respectively. The question of the reality of these fluctuations was considered, and tested by comparing their effects in producing apparent fluctuations of slightly different times, such as the well-known sun-spot period of about eleven years. The agreement was such as to make it probable that the two first-mentioned fluctuations are the two prevailing periodicities. The approximate values of some of their part-periods had been computed, and the totals gave a fair approximation to all the more striking changes that have occurred in the rainfall at the Observatory from year to year for the last sixty years. The author concluded that the coincidences were sufficient to warrant a careful investigation of the exact times of the chief fluctuations, and a computation of the magnitude of their sub-periods. He intends to prosecute the research.

DIARY OF SOCIETIES.

THURSDAY, NOVEMBER 29.

GOLDSMITHS' INSTITUTE CHEMICAL SOCIETY, at 8.30.—The Profession of an Industrial Chemist: Dr. J. Lewkowitsch.

MONDAY, DECEMBER 3.

VICTORIA INSTITUTE, at 4.30.—The Proceedings of the Congress for the History of Religion, Paris: Theophilus G. Pinches.

TUESDAY, DECEMBER 4.

SOCIETY OF ARTS, at 8.—Electric Oscillations and Electric Waves: Prof. J. A. Fleming, F.R.S.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Paper to be discussed*: Machinery for the Manufacture of Smokeless Powder: Oscar Guttmann.——*Papers to be read, time permitting*: The Signalling on the Waterloo and City Railway; and Note on the Signalling of Outlying Siding Connections: A. W. Szlumper.—Signalling on the Liverpool Overhead Railway: S. B. Cottrell.

FRIDAY, DECEMBER 7.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Dock Gates: F. K. Peach.

GEOLOGISTS' ASSOCIATION, at 8.—The Zones of the White Chalk of th English Coast. II. Dorsetshire: Dr. A. W. Rowe.

CONTENTS.

THURSDAY, DECEMBER 6, 1900.

THE RECENT SPORTING EXPERIENCES OF MR. SELOUS.

Sport and Travel, East and West. By F. C. Selous. Pp. ix. + 311; illustrated. (London: Longmans, Green, and Co., 1900.)

HAVING seen, or shot, practically every species of great game in South and South-east Africa, the indefatigable author of the volume before us has devoted several seasons in the closing decade of the century to hunting-trips in the northern hemisphere. These expeditions included three trips to Asia Minor in search of the wild goat, the Armenian sheep, and the Asiatic red deer, and two to the Rocky Mountains, where wapiti, mule-deer, white-tailed deer, prongbuck and lynx fell to the practised aim of the veteran hunter. Not that Mr. Selous is by any means merely a hunter; he is likewise an observant field-naturalist and an enthusiastic egg-collector, having contributed many years ago an important paper on African antelopes to the *Proceedings* of the Zoological Society, while his recent expeditions to Asia Minor have furnished material for an ornithological paper to the *Ibis*. It is perhaps needless to add that such an experienced hunter may be depended upon not to shoot animals for the mere sake of slaying, and that after obtaining a few fine examples of the species he encountered for the first time to add to his splendid collection at Alpine Lodge, Worplesdon, and occasionally killing an individual or two for the commissariat, Mr. Selous has always been content to stay his hand.

To compare in point of interest his recent experiences with those detailed in his "Hunter's Wanderings in Africa" would perhaps be unjust, if only for the reason that the number of species of game animals to be encountered in the lands he has lately visited falls immeasurably short of those which have their home on the South African veldt. Then, too, we have no such mighty beasts as the white rhinoceros and the African elephant to enthral the reader's interest in the volume. And it must also be remembered that hunting in the "Rockies' has been made familiar to us by the writings of sportsmen like Roosevelt, whereas at the date Mr. Selous gave to the world his unrivalled South African experiences, there had been comparatively little written on the subject of the large game of the interior since the trips of Gordon Cumming, Andersson and Oswell.

Nevertheless, in spite of having the prestige of his earlier *magnum opus* to contend against, it cannot be gainsaid that on the present occasion Mr. Selous has succeeded in producing a volume calculated to attract a large circle of readers, and these, too, not only from among sportsmen and travellers, but from naturalists as well. To the latter, at any rate, the greatest interest of the book is concentrated on the part devoted to shooting in Asia Minor, in which district we have a less full knowledge of the animals than is the case with those of North America. One of the points where the author has been of undoubted service to naturalists is in regard to his description of the seasonal colour-changes of the wild goat; such seasonal changes in the colour of horned game animals having till late years attracted comparatively little attention among zoologists. According to the description given by Mr. Selous, it appears that in the summer coat these goats are of a reddish-brown colour, with the broad dark shoulder-stripe, which becomes so conspicuous in winter, almost entirely wanting, the black beard being at the same time comparatively short. In winter, on the other hand, the old bucks have the general ground-colour nearly white, although the flanks and under-parts are somewhat darker, being of a light sandy-yellow. In marked contrast to these pale tints stands out the broad black shoulder-stripe and dorsal streak, while the beard becomes long and flowing.

It is interesting to note that, in spite of his full acquaintance with all the splendid South African representatives of the antelope tribe, Mr. Selous pronounces the wild goat of the Maimun Dagh to be one of the handsomest and most striking of all game animals, although he is careful to avoid making invidious comparisons. In its native mountains the wild goat is, indeed, one of the most wary of horned animals, and as it is by no means plentiful, its pursuit demands all the patience and resources of the skilled stalker. And the sympathies of all sportsmen will be with Mr. Selous when they read his account how, after many failures and losing one good head, he eventually killed a magnificent old buck, only to discover that it was minus one of its splendid horns. The statement, on p. 27, that the wild goats of the Musa Dagh (on which there is but a single spring of fresh water) frequently descend to the beach and drink sea-water, is certainly very remarkable, for although it is now well known that many species of ruminants can exist for long periods, if not altogether, without drinking, yet this is the first instance that has come under our notice of their resorting to the ocean for water. Although, in the absence of an index, it is a little difficult to be certain that we have not overlooked a passage, the author does not seem to have been successful in "bagging" the Armenian wild sheep, although he obtained several fine examples of the ollin, or Asiatic race of the red deer.

To visit the mountains and prairies of the north-western states of America appears to have been a life-long dream of Mr. Selous—a dream that was never realised till long after the bison had disappeared from the latter, and the numbers of the wapiti had been deplorably reduced in the former. In regard to the skulls of the bison which the author met with so commonly in the Bighorn basin, we are told that many of these still retained the sheaths of the horns and even fragments of skin and hair after an exposure of at least fourteen years. "I should certainly never have believed," he writes, "that even the hardest of bone, let alone horn and skin, could have withstood the ravages of time and exposure so well. In the climate of Africa no organic matter lasts very long when exposed to the weather, and even the skull and leg-bones of an elephant would, I think, crumble to dust and absolutely disappear in less than fifteen years from the date of the animal's death." At the present time, these observations are of considerable interest in connection with the skin of the ground-sloth preserved in a Patagonian cave.

Evidence of the former abundance of the wapiti and

the mule-deer in the same district was afforded by the number of bleached antlers which marked the line of the great spring migration, when the wapiti were returning to the mountains from their winter feeding-grounds on the plains. At the present day, these noble deer are unknown on the low-grounds of the Bighorn basin, and the few survivors have to make shift as best they can during the dreary winter months in the mountains, from among the pine forests of which they emerge as seldom as possible.

Mr. Selous was fortunate enough to obtain some very fine heads of wapiti, white-tailed deer and mule-deer, one head of the latter being a remarkably good specimen, and notable on account of the relatively narrow span of the antlers. To one expression which the author is very fond of using—to wit, a "bull" wapiti—we are fain to take exception, the term "stag" being the proper one to employ in this connection. And here we may venture to point out to the author, in connection with a statement on page 166, that naturalists of the present day (whatever may have been the practice with their predecessors) are not in the habit of translating generic terms into English, and that, consequently, there is no objection to the application of the name Antilocapra to the American prongbuck, on the ground that it indicates an animal midway between an antelope and a goat. Such names should be regarded as mere abstract terms without any definite meaning. And, while we are fault-finding, it may be mentioned that there are a few little slips in nomenclature which might advantageously have been avoided. The rough-legged buzzard, for instance, is not an Aquila (p. 140), while Speotyto, and not Speotitis (p. 145), is the proper title for the little American ground-owls. It may be added that it would have been a decided improvement to the book if, instead of making the title the heading of every page, the chapter-headings had been employed for the right-hand pages.

A reviewer is always expected to pick some holes in a book, but it may be candidly stated that the foregoing are all the faults we have to find with the one before us. To those who contemplate a trip to either of the districts visited by Mr. Selous, as well as to those stay-at-home people who prefer to hear of stirring adventures by field and flood when comfortably seated by their own firesides, rather than undergo the inseparable hardships and toils themselves, we can confidently recommend "Sport and Travel" as an attractive and interesting volume, written by one who is at the same time a keen sportsman and an intelligent and thoughtful observer. R. L.

THE COMPARATIVE HISTOLOGY OF VERTEBRATES.

Lehrbuch der vergleichenden mikroskopischen Anatomie der Wirbeltiere. Herausgegeben von Dr. Med. Albert Oppel—Dritter Teil. Pp. x. + 1180. (Jena: Gustav Fischer, 1900.)

PROF. OPPEL has set himself the colossal task of furnishing a succinct account of the comparative histology of vertebrates, and the volume before us is the third instalment towards the attainment of that end. The two former parts, which appeared in 1896 and 1897, dealt respectively with the comparative structure of the stomach and of the gullet and intestines. The present is concerned with the remainder of the alimentary canal, viz., the mouth, including the tongue and salivary glands (but exclusive of the teeth, which are referred to a later publication in which the skeleton will be dealt with) and the large glands whose ducts open into the commencement of the intestine, viz., the pancreas and liver. The extent of the undertaking will be manifest when we mention that the account of these subjects requires nearly 1200 large octavo pages, with 679 illustrations in the text and ten coloured lithographic plates, and that there is a bibliographical list comprising several hundred books and papers, each one of which is referred to in the text, and all of which are given with their full title and references; so that the possession of this alone would render the book of inestimable value to any one working at any part of the subject with which it deals.

As we have pointed out in noticing the parts of Prof. Oppel's work which have already appeared, the author has not attempted to verify all the statements and descriptions which he gives; such verification would indeed be an impossible task when we consider the enormous amount of material which has accumulated upon the subject, even within recent years. Nevertheless, there are several points in the present volume upon which Prof. Oppel has made personal observations, and although these are not published in this book for the first time, their appearance tends to give an air of originality to a work which, in the main, must necessarily be a compilation, however critically the matter which it contains is dealt with; but it will be easily understood that where, as in a work of this character, conciseness must be a main object there cannot be much room for criticism.

A feature of the work is the chronographical order in which the results of investigation upon each subject dealt with are put before the reader, an arrangement which gives a special interest of a historical character to many of the descriptions. This is well exemplified in the chapters dealing with the relation between the structure of glands and their condition of activity, in which, as in many other parts of the book, the author contrives to introduce points of high physiological interest into a work the chief aim of which is no doubt morphological. Where all is excellent it is not easy to particularise; but certain parts are especially dealt with in a masterly manner, as, for example, the structure and relations of the tonsils and similar lymphatic tissues in the mouth and pharynx, the papillæ of the tongue and the distribution of taste buds upon them, the structure of the lingual and salivary glands and pancreas in mammals, including the changes which they undergo during secretion, their secretory capillaries, their nerves and nerve-endings. The account of the pancreas embraces, not only a minute description of the glandular substance proper and of the changes which its cells undergo in different physiological conditions, but also a careful description of the intertubular islands which were first described by Langerhans, and which have recently attracted attention on account of the possibility, which has been expressed by more than one writer, that the influence which that gland exerts upon the carbohydrate metabolism of the body (its entire removal is always followed by severe diabetes) may be dependent upon an internal secretion produced by the cells in question.

The part which is devoted to the liver opens with a comparison of the structure of that with other glands, and is followed by a historical account of the discovery of the bile canaliculi, which furnishes an excellent example of the value of applying the methods of physiology to the elucidation of structure. The treatment of the liver cell alone occupies some forty pages, although this is a subject which, in most text-books of histology, is considered to be sufficiently dealt with in as many lines. Another important part of this section, not merely from a morphological but also from a pathological point of view, is that devoted to the connective tissue of the lobules, which was originally shown by von Fleischl (working with Ludwig) to be so abundant; a fact which has been confirmed and extended by several observers employing modern histological methods. Like its predecessors, this volume is a storehouse of information upon the subjects of which it treats, and must remain for many years an indispensable work of reference, not only to the comparative anatomist and histologist, but also to the physiologist. E. A. S.

OUR BOOK SHELF.

Flies Injurious to Stock. By Eleanor A. Ormerod, LL.D. Pp. 80. (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd., 1900.)

MISS ELEANOR A. ORMEROD continues her useful work of popularising the information which has been acquired concerning the life-histories of injurious insects by issuing, in a form accessible to all, an account of the principal dipterous pests which infest stock.

The book does not pretend to be a contribution to science, for Miss Ormerod's own important observations on the "Warble-fly" have been several times previously published, and the rest of the work is mainly compiled from various authors whose papers are duly referred to in footnotes.

The Hippoboscidæ are represented by the "forest-fly" and the so-called "sheep-tick," but most of the book is devoted to an account of the Tabanidæ or "gad-flies" and the Œstridæ or "bot-flies," and the writer tries to make clear the differences in structure and habits between the members of these two families. Much general ignorance exists with regard to the common biting flies, and the brief account of them here given will, we imagine, be particularly welcome. Considering the frequency of their occurrence, remarkably little is known of the early history of some of these insects, but Miss Ormerod is surely in error in stating that that of *Haematopota* is unknown, for the larva has been described and figured by Perris.

The Œstridæ, economically the most important family, naturally come in for the fullest treatment. Errors which have crept into the usual accounts of the "sheep's nostril fly" are corrected. Larvæ, not eggs, are laid in the sheep's nostril, but though they work up into the nasal passages, they never, as is often stated, reach the brain.

A second horse bot-fly which occurs in this country, *Gastrophilus haemorhoidalis*, might have been mentioned, especially as it is more easy of detection and more susceptible of treatment than the common species.

The otherwise excellent account of the "warble-fly" is marred by the incorporation of a large amount of correspondence, the gist of which might have been compressed into a few lines. However appropriate the inclusion of these letters in Miss Ormerod's original papers on the subject, they seem out of place in a *résumé* such as that before us.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Value of Magnetic Observatories.

IN answer to those who consider that the magnetic results obtained at Kew Observatory are of little or no practical value, I would offer the following remarks for their consideration. The railway engine driver may run his 70 miles an hour on rails, certain as to being on the right road, and in like manner the electric tram car driver may keep in the right direction.

The sailor, however, on the trackless ocean, has only his compass to guide him, at best directed by that unstable magnet the earth. But the earth by induction transforms his iron or steel ship into a still less stable magnet, which not only disturbs the compass on board but permanently reduces the value of the earth's directive force on that compass by ·1 or ·2 of that observed on land.

Fortunately, as the knowledge of terrestrial magnetism increased, men of science were gradually enabled to solve the at one time knotty problem of a ship's magnetism, and the seaman can now run his vessel over twenty knots an hour in safety on a dark night. Without a knowledge of terrestrial magnetism, the now universal iron or steel ship would have been almost an impossibility, and the faster ships go the more necessary does that knowledge become, to wit in the navigation of the St. Lawrence and English Channel. The sailor is continually asking for charts of the magnetic declination to be brought up to date; Kew and other magnetic observatories help largely in this direction.

Moreover, a theory of terrestrial magnetism is much wanted which (letting alone other possibilities) would enable us to provide accurate charts of the magnetic elements years in advance, in the same manner that the "Nautical Almanac" is prepared. Hence the importance of Kew as a valuable link in the chain of magnetic observatories, which has already been reduced by the destruction caused by electric tramways.

Blackheath, S.E. ETTRICK W. CREAK.

Huxley's Ancestry.

WITH reference to Lord Avebury's reminiscences of Huxley, and the summary of his views concerning British races, it may be of interest to quote Huxley's account of his own racial characters, as contained in a private letter written ten years ago: "My father was a Warwickshire man; my mother came of Wiltshire people. Except for being somewhat taller than the average of the type, she was a typical example of the 'Iberian' variety—dark, thin, rapid in all her ways, and with the most piercing black eyes I have ever seen in anybody's head. Mentally and physically (except in the matter of the beautiful eyes) I am a piece of my mother, and except for my stature, which used to be 5 feet 10, I should do very well for a "black Celt" —supposed to be the worst variety of that type. My father was fresh-coloured and grey-eyed, though dark-haired, good-humoured, though of a quick temper, a kindly man, rather too easy-going for this wicked world. There is a vein of him in me, but the constituents have never mixed properly. . . . I know of Huxleys in Staffordshire, Worcestershire and Wales, and I incline to think that the Huxleys of Huxley [Cheshire] are responsible for most of us, and that, upon the whole, we are mainly Iberian mongrels, with a good dash of Norman and a little Saxon." This was written for my private information, as bearing on certain inquiries into "genius" and race, but there can be no objection to its publication now.

HAVELOCK ELLIS.

Quartz-Calcite Symmetrical Doublet.

AT the Bradford meeting of the British Association, Section A, I offered to lend this lens for purposes of research to any investigator who would satisfy me as to his qualification for taking the necessary care of it. I am now ready to do so.

Oaklands, Chard, November 26. J. W. GIFFORD.

ON SOLAR CHANGES OF TEMPERATURE AND VARIATIONS IN RAINFALL IN THE REGION SURROUNDING THE INDIAN OCEAN.[1]

II.

Indian Rainfall. S.W. Monsoon, 1877–1886.

IT will be clear from what has been stated that our object in studying rainfall was to endeavour to ascertain if the + and − temperature pulses in the sun were echoed by + and − pulses of rainfall. The Indian rainfall was taken first, not only because in the tropics we may expect the phenomena to be the simplest, but because the regularity of the Indian rains had broken down precisely when the widened line observations showed a most remarkable departure from the normal.

It was also important for us to deal with the individual observations as far as possible, because it was of the essence of the inquiry to trace the individual pulses if they were found. Hence the S.W. monsoon was, in the first instance, considered by itself, because although Eliot holds that the winter rains (N.E. monsoon) are due to moisture brought by an upper S W. current,[2] their incidence is very different and their inclusion might mask the events it was most important to study.

The first investigation undertaken was the study of the rainfall tables published by the Meteorological Department of the Government of India. These were brought together by Blandford down to the year 1886.[3] As the widened line observations were not begun at Kensington till 1879, the discussion was limited in the first instance to the period 1877–1886 inclusive, embracing the following changes in solar temperature, occurring, as will be seen, between two conditions of mean solar temperature :—

Mean	− pulse	Mean	+ pulse	Mean
1876	1877–1880	1881	1882–1886	1886–1887

Bearing in mind that the intensity of the + pulse may in some measure be determined by the solar disturbances, which for the present are registered by spotted area, it is important to point out that the preceding maximum in 1870 was remarkable for obvious indications of great solar activity.[4]

It soon became evident that in many parts of India the + and − conditions of solar temperature were accompanied by + and − pulses producing pressure changes and heavy rains in the Indian Ocean and the surrounding land. These occurred generally in the first year following the mean condition, that is, in 1877–8 and 1882–3, dates approximating to, but followed by, the minimum and maximum periods of sun-spots.

Meldrum, as far back as 1881,[5] referred to "the extreme oscillations of weather changes in different places, at the turning-points of the curves representing the increase and decrease of solar activity."

It was especially in regions such as Malabar and the Konkan when the monsoon strikes the west coast of India, that the sharpness and individuality of these pulses was the most obvious.

One method of study employed has depended upon Chambers's view (*Indian Meteorological Memoirs*, vol. iv. Part 5, p. 271) that the S.W. monsoon depends upon the oscillations of the equatorial belt of low pressure up to 31° N. lat. at the summer solstice. The months of rain-receipt on the upward and downward swing will therefore depend on the latitude, and these months alone have been considered.

We began by taking elevated stations in high and low latitudes.

Leh Lat. 34° N. 11,500 feet	The 1881 pulse (in July) was the heaviest recorded (1·77 inches) save one in 1882 ; the rainfall was nearly as high. The pulse felt in 1878 was the highest of all.
Murree Lat. 33° N. 6344 feet	The 1881 pulse (Aug.) is high, but is followed by a higher next year. The 1878 pulse (Aug.) is highest of all.
Newera Eliya Lat. 7° N. 6150 feet	Taking the fall in July and Aug. The 1881 pulse occurs in 1882, and is highest. Next comes the pulse in 1878.

It must also be stated that if we take the sun-spot maximum, including the period we have chiefly discussed (1877–1886), as normal, it is found that there are variations in rainfall accompanying the preceding and succeeding maxima of 1870 and 1893. This variation indicates the existence of a higher law, but there has not been time to discuss them thoroughly enough to justify any definite statements about them.

The Rainfall of "Whole India."

The next step was to work on a longer base, and for this purpose Eliot's whole India table of rainfall, 1875–1896 (NATURE, vol. lvi. p. 110), embracing both the S.W. and N.E. monsoons, being at our disposal, was studied.

It was anticipated that such a table, built up of means observed over such a large area and during both monsoons, would more or less conceal the meaning of the separate pulses observed in separate localities ; this we found to be the case. But, nevertheless, the table helped us greatly, because it included the summation of results 9 years later than those included in Blandford's masterly memoir. Predominant pulses were found in 1889 and 1893, following those of 1877–8 and 1882–3. So that it enabled us to follow the working of the same law through another sun-spot cycle, the law, that is, of the mean solar temperature being followed by a pulse of rainfall.

Mean sun	Rain pulse
1876	− 1878
1881	+ 1882
1886–7	− 1889
1892	+ 1893

The main feature of this table is the proof of a tremendous excess of rainfall in 1893—by far the greatest excess of all (percentage variation, +22). This was far greater than the excess in 1882.

The next remarkable excess occurs in 1878 (percentage variation, + 15).

The pulses in the period stand as follows :—

	Percentage variation	Heat pulse	Remark
Min. 1878	+15	−	Years after rise of iron lines.
Max. 1882	+ 6	+	Years after rise of unknown lines.
Min. 1889	+ 6	−	Years after rise of iron lines.
Max. 1893	+22	+	Years after rise of unknown lines.

[1] By Sir Norman Lockyer, K.C.B., F.R.S., and W. J. S. Lockyer, M.A. (Camb.), Ph.D. (Gött.) Paper read before the Royal Society on November 22. Continued from p. 109.

[2] Report, 1877, p. 125.

[3] "Indian Meteorological Memoirs," vol. iii.

[4] "The year 1870 was characterised by an exuberance of solar energy, which is without parallel since the beginning of systematic observations (*i.e.* since 1825). The number of observed groups far exceeds that of any previous year, and it appears also from a cursory comparison with the maximum year's observations, as recorded by Hofrath Schwabe, that the magnitude of the different groups, as well as the average amount of spotted surface during any period of the year, is unprecedented." (*Monthly Notices*, vol xxxi. p. 79, Warren de la Rue, B. Stewart, B. Loewy.)

The table which the authors of this paper give shows that during the year, although observations of the sun were made on 213 days out of the 364, there was no day without spots recorded. In fact, during the whole year no less than 403 new groups ol spots were noted, thus showing us that on the average there was more than one new group per diem.

The authors further remark, "A very remarkable feature of the groups observed during the year appears to be their extraordinary lifetime. . . an exceedingly large number of groups completed 3, 4, and even more revolutions before finally collapsing."

[5] "On the Relations of Weather to Mortality, and on the Climatic Effect of Forests."

The variations in the intensities of the pulses of rain at the successive maxima and minima are very remarkable, and suggest the working of a higher law, of which we have other evidence. But, putting this aside for the present, it should be pointed out that even normally we should not expect the same values for the rainfalls in 1882 and 1893, because the amount of spotted area was so different, 1160-millionths of the solar surface being covered with spots in 1883, and 1430 in 1893.

The very considerable variation in the quantity of snowfall on the Himálayas has often been pointed out by the Indian meteorologists. We have, therefore, used the "whole India" curve between 1875 and 1896, to see whether the sun pulses, which we have found to be bound up with the Indian rainfall, are in any way related to the snowfall as might be expected.

The Himálayan snowfall beyond all question follows the same law as the rain, the values occurring at the + and − pulses, as under, being among the highest :—[1]

		inches
−	1867-8 ...	134
+	1871-2 ...	110
−	1877-8 ...	207
+	1882-3 ...	81

From these tables it follows that both in rainfall and snow the quantity is increased in the years of the rise both of the unknown and iron lines.

Other Rainfalls.

Being in presence of pulses of rainfall in India during the south-west monsoon, corresponding with pulses of solar change, it became necessary to attempt to study their origins. We may add that other pulses were traced, especially one in 1875, but the simplest problem was considered alone in the first instance.

The rainfalls at the Mauritius, Cape Town and Batavia were collated to see if the pulses felt in India were traceable in other regions surrounding the Indian Ocean to the south and east.

The Mauritius Rainfall.

The rainfall of Mauritius has been obtained by utilising the results that have been published in the Blue Books [2] issued by the Royal Alfred Observatory since the year 1885. The volume for 1886 gives the yearly total rainfall for every station that was then in use from 1861 up to the year 1885, and these values have been employed ; since then the yearly values have been obtained direct from each of the yearly volumes subsequently published, *i.e.* to the end of the year 1898.

It was at first thought that the total Mauritius rainfall could be fairly obtained by employing for the period between 1861 and 1886 the means of several stations as given by Meldrum,[3] and continuing the values from the observations published in the more recent yearly volumes.

It was found, however, that from 1861–1880 the rainfall was obtained from the observations of four stations, while from 1871–1886 the observations from eight stations were employed.

As a study of all the published data showed that more stations might be utilised in determining the total rainfall of Mauritius, it was decided to discuss all the observations afresh, and make use of as many as possible.

To this end the records of twenty-eight stations, situated in six different districts, were chosen, and the total rainfall for each year obtained. It is only natural that the number of rain-gauge stations in the early year of 1860 was not so numerous as that of more recent years ; the facts may be stated as follows :—

Years.	Mean yearly rain-fall variation from normal	No. stations used.	Years.	Mean yearly rain-fall variation from normal.	No. stations used.
	Inches.			Inches.	
1861	+26·6	1	1880	−19·3	23
1862	−10·2	4	1881	− 7·3	25
1863	+ 9·6	6	1882	+16·6	25
1864	−12·2	8	1883	+ 1·8	26
1865	+22·6	10	1884	−12·4	25
1866	−18·2	10	1885	− 9·8	26
1867	− 6·6	11	1886	−35·3	26
1868	+27·1	11	1887	− 4·2	27
1869	− 3·3	12	1888	+22·3	26
1870	− 3·6	12	1889	+18·4	24
1871	−18·9	13	1890	+ 1·2	25
1872	− 7·0	13	1891	+ 1·4	26
1873	+10·3	13	1892	+ 5·1	19
1874	+17·4	17	1893	− 7·4	24
1875	+ 3·0	15	1894	− 0·6	24
1876	− 6·5	17	1895	+10·0	21
1877	+31·4	19	1896	+17·6	22
1878	− 3·8	22	1897	−19·6	24
1879	− 5·2	22	1898	− 2·1	24

With regard to the general rainfall of Mauritius throughout the year, it may be stated that on the average the most rainy months are from December to April, both months inclusive.

The months of November and May are those in which the daily rainfall is increasing and diminishing respectively. Sometimes in July or August there is a slight tendency for a small increase.

The Mauritius Rainfall Curve for the period 1877–1886.

In plotting the Mauritius rainfall curve for the period 1877–1886, it was observed that the curve is of a fairly regular nature, showing alternately an excess and deficiency of rainfall.

The highest and lowest points of the curve will be gathered from the following table :—

Year.	Maximum.	
	Excess.	Deficiency.
1877	31·4	—
1880	—	19·3
1882	16·6	—
1886	—	35·3

Comparing the times of occurrence of the two pulses of rainfall at Mauritius with the times of the crossings of the known and unknown lines, it is found that the Mauritius maximum rainfall of 1877 occurs about a year after the rise of the known lines in 1876. The next Mauritius pulse of rainfall in 1882 follows the succeeding crossing, when the unknown lines are going up, also about a year later.

Comparison of the Mauritius Rainfall with those of Leh, Murree and Newera Eliya for the period 1877–1886.

The most prominent feature of the Mauritius rainfall for this period was the great excess in the years 1877 and 1882.

1 *I.M.M.*, vol. iii. p. 235.
2 "Mauritius Meteorological Results."
3 1861–1880. Relations of Weather to Mortality, &c., 1881, p. 36. 1871–1886. Annual Report of the Director of the Royal Alfred Observatory for 1886, p. 18.

Both of these pulses have corresponding maxima in the curves for the rainfalls of Leh, Murree and Newera Eliya, the dates of these in all three cases being 1878 and 1882.

The delay of about a year in the effect of the Mauritius pulse being felt in Ceylon and India is exactly what would be expected if the rain at sun-spot minimum comes from the south, as has been surmised.

The fact that the pulses at Mauritius, Ceylon and India in 1882 occur simultaneously is very strong evidence in favour of an origin in the equatorial region itself for the Indian rain at sun-spot maximum. The pulse at maximum in the Indian south-west monsoon may depend to a large extent upon the action of the excess of solar heat on the equatorial waters to the south of India, and not on an abnormal effect on the south-east trade.

We have found that there was a defect of the usual rainfall at Mauritius in 1892–3, and yet the rain supply in India was in excess.

from time to time in the Southern Ocean. In his "Annual Summary" for 1896 he wrote as follows:—

"It has apparently been established in the discussion that the variations of the rainfall in India during the past six years are parallel with, and in part, at least, due to variations in the gradients, and the strength of the winds in the south-east trade regions of the Indian Ocean. The discussion has indicated that there are variations from year to year in the strength of the atmospheric circulation obtaining over the large area of Southern Asia and the Indian Ocean, and that these variations are an important and large factor in determining the periodic variations in the rainfall of the whole area dependent on that circulation, and more especially in India. It has also been indicated that these variations which accompany, and are probably the result in part of abnormal temperature (and hence pressure) conditions in the Indian Ocean and Indian monsoon area may be in part due to conditions in the Antarctic Ocean, which also

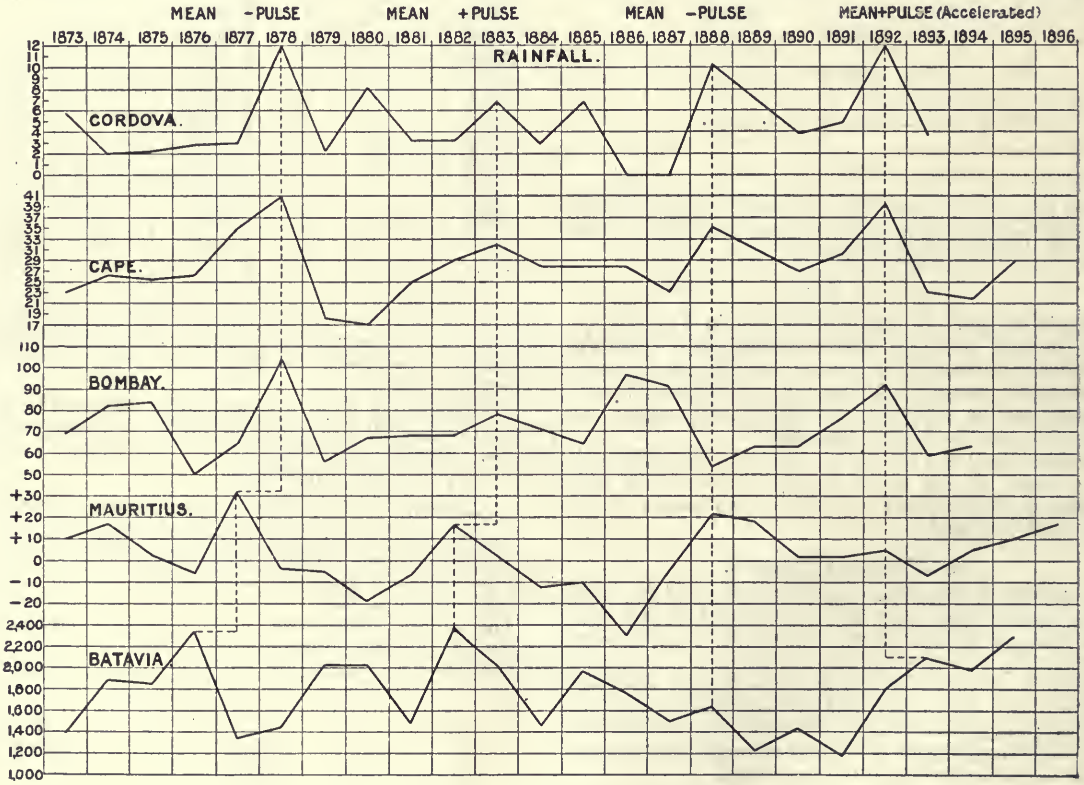

FIG. 1.

RESULT OF THE COMPARISON OF RAINFALL.

The + and – Pulses.

It seems quite certain that we are justified in associating the 1878 pulse of rainfall during the south-west monsoon in India with the rainfall common to Mauritius, Batavia and the Cape at that date; that in all cases the rain has been associated with some special condition connected with the south-east trade in the Indian Ocean.

The rainfall of Cordoba suggests that the same trade wind in the Atlantic Ocean was similarly affected at the same time.

The Cause of the – Pulse.

Mr. Eliot long ago conjectured that the rainfall of India was profoundly modified by events taking place

determine the comparative prevalence or absence of icebergs in the northern portions of the Antarctic Ocean."

We have begun an investigation into the pressure changes which have been recorded in this region, but it will be some time before it is finished. The idea underlying the inquiry is that the reduced solar temperature may modify the pressure so that the high pressure belts south of Mauritius may be broken up and thus allow cyclonic winds from a higher latitude to increase the summer rains as they certainly were increased at the normal minima of 1877 and 1888.

It has been shown that the – pulse is felt in India about a year later than it commences action in the southern oceans; while in some cases the + pulse is felt almost simultaneously in India and at the southern stations.

The Rainfall at the Cape, Batavia and Cordoba for the Period 1877–1886.

Each of the curves illustrating the rainfall for the Cape and Cordoba for this period shows two prominent maxima in the years 1878 and 1883; these correspond nearly with the + and − pulses of solar temperature. Comparing them also with the Bombay and Mauritius curves for the same period, it is found that the pulses indicated at Bombay occur simultaneously with those of 1878 and 1883, but in the case of Mauritius the effect of each of the pulses is felt about a year or so earlier, namely 1877 and 1882 (Fig. 1).

The rainfall curve for Batavia for this period has its most prominent maximum in the year 1882, like that of Mauritius, thus preceding by a year the pulse felt at the Cape, Cordoba and Bombay in 1883.

The Time Conditions of the Pulses.

The various curves which we have drawn for the purposes of study have been compiled from yearly means, generally to be the case. Thus after the mean solar temperature of 1876, the − pulse was felt first at Mauritius, then in India and the Cape. After the mean of 1881, the + pulse was felt first at Mauritius, then in India and the Cape. Cordoba felt both pulses in the same year as India and the Cape.

Subsidiary Pulses.

In a normal sun-spot curve we find a sharp rise, generally taking three or three and a half years, to maximum, and a slow decline to minimum, on which the remaining years of the cycle are spent.

The curve on the upward side rises generally regularly and continuously; on the downward portion the regularity of the curve is very often broken by a "hump" or sudden change of curvature. There has not yet been a complete discussion of the number and character of the prominences associated with the spots during the cycle; we have found, however, that the "hump" in the sunspot curve in 1874 was accompanied by a remarkable increase in the number of eruptive prominences.

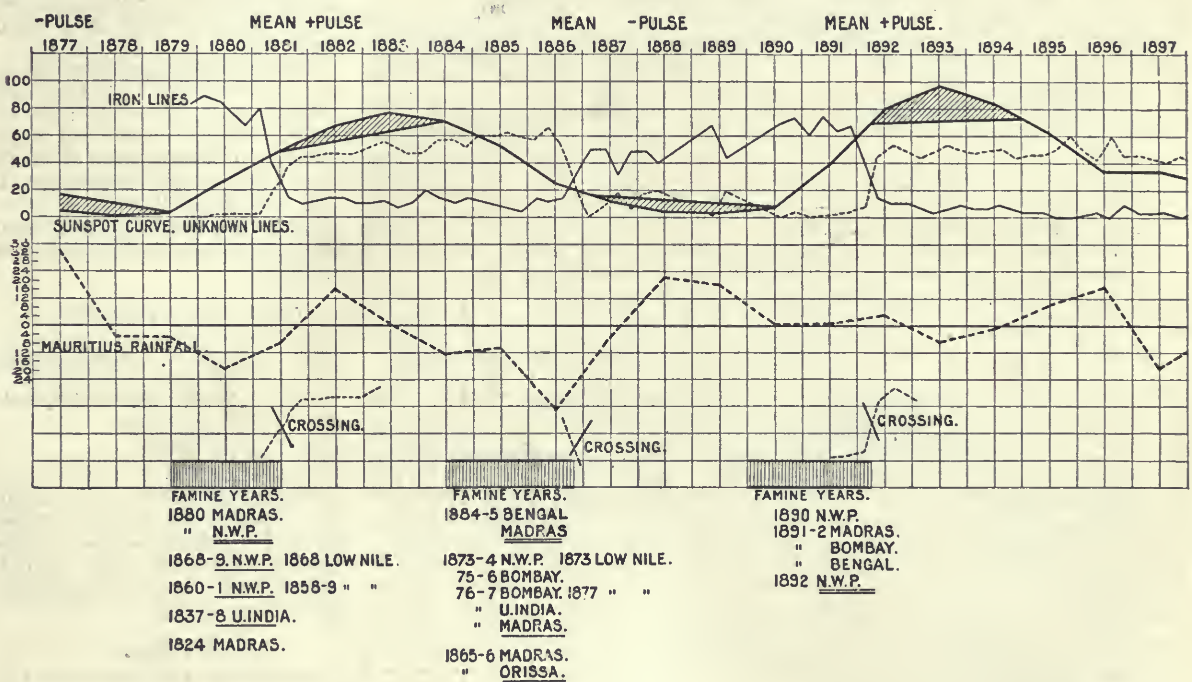

FIG. 2.

and, so far, in these curves the rainfall in months has not been considered. That will have to come later. Hence if the rainfall which most influences the yearly mean occurs in the last three months at one place, and in the first three months of the next year at another, they are shown as being a year apart, whereas they have actually been continuous.

With regard to the travel of the pulses over large areas under the influence of the S.E. trade, it may be gathered from the pressure charts that the + and − conditions of pressure are apt to lie over the centres of land and water areas, and not generally over coast lines. In the case of water surfaces, the effect of a sudden change in the solar radiation on the pressure might be expected to be felt not at the point where the pressure is least or greatest at the time, and of the most general type, but where the equilibrium is most unstable. On the other hand, more time would be required for the new pulse to establish itself where the conditions are more complicated.

Hence we should expect the pulses to be felt first in the eastern part of the southern ocean, and this seems

We have already referred, in discussing the Indian rainfall, to a remarkable intensification of the south-west monsoon in 1874–5, the effect of which is especially noticeable in the rainfall of the Konkan and North-West Provinces, and we have come to the conclusion that we must consider all these events as due to a common cause, that is, to a subsidiary solar pulse. We propose to return to this subject in a subsequent communication, after inquiries have been completed relating to 1885–6 and 1896–7.

The Intervals between the Pulses.

There will obviously be intervals between the ending of one pulse and the beginning of the next, unless they either overlap or become continuous.

The + and − pulses, to which our attention has been chiefly directed, are limited in duration; and when they cease the quantity of rain which falls in the Indian area is not sufficient without water storage for the purposes of agriculture; they are followed, therefore, by droughts, and at times subsequently by famines.

Taking the period 1887–89 we have (Fig. 2)

Rain from − pulse	77, 78, 79 (part)
No rain pulse	79 (part), 80 (central year), 81 (part)
Rain from + pulse	81 (part), 82, 83, 84 (part)
No rain pulse	84 (part), 85, 86 (central years), 87 (part)
Rain from − pulse	87 (part), 88, 89

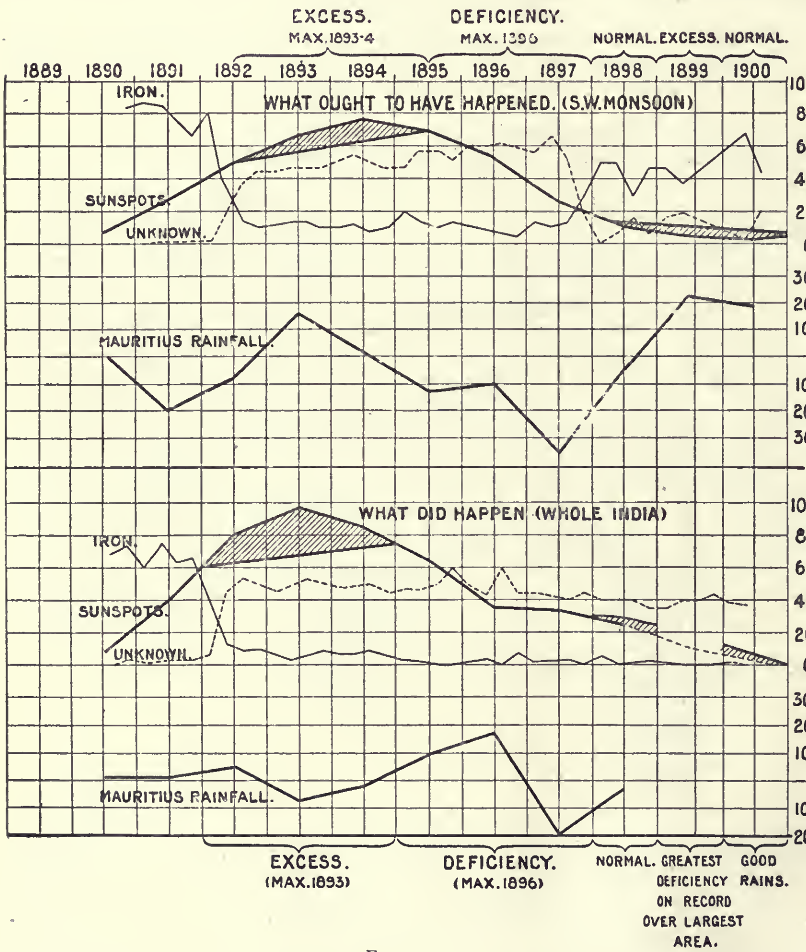

FIG. 3.

The duration of these + and − pulses of rainfall was determined in the first instance by the Mauritius rainfall, which shows both pulses; and later from the Malabar rainfall, which perhaps shows the effect of the south-west monsoon in its greatest purity.

All the Indian famines since 1836 (we have not gone back further) have occurred in these intervals, carried back in time on the assumption of an 11 year cycle.

The following tables show the result for the two intervals:—

The interval between the pulses, taking 1880 *as the central year, on the upward curve.*

1880, Madras famine.
N.W.P. famine.
1880 − 11 = 1869, N.W.P. famine (1868-9).
1869 − 11 = 1858, N.W.P. famine (1860).
1858 − 11 = 1847.
1847 − 11 = 1836, Upper India famine (1837-8). (Great famine).

The interval between the pulses, taking 1885-6 *as the central years, on the descending curve.*

1885-6 {Bengal famine, Madras famine} (1884-5).
1885-6 − 11 = 1874-5, N.W.P. famine (1873-4).
Bombay famine (1875-6).
{Bombay famine, Upper India famine} (1876-7).
1874-5 − 11 = 1863-4, {Madras famine, Orissa famine} (1865-6).
1863-4 − 11 = 1852-3, Madras famine (1854).

It is clear from the above table that if as much had been known in 1836 as we know now, the probability of famines at all the subsequent dates indicated in the above tables might have been foreseen.

The region of time from which the above results have been obtained extended from 1877 to 1886. The next table will show that if the dates, instead of being carried back, are carried forward, the same principle enables us to pick up the famines which have devastated India during the period 1886-97.

Same intervals, going forward.

1880.
+11 1891, N.W.P. famine (1890).
{Madras famine, Bombay famine, Bengal famine} (1891-2).
1885-6
+11 1896-7, General famine.

This result has arisen, so far as we can see, from the fact that the + and − pulses included in the period 1877-1886 were normal, that is, were not great departures from the average.

Nile Floods.

After we had obtained the above results relating to the law followed by the Indian famines, we communicated with the Egyptian authorities with a view of obtaining data for the Nile Valley.

We have since found, however, from a memorandum by Eliot,[1] that Mr. Willcocks, in a paper read at the Meteorological Congress at Chicago, remarked that "famine years in India are generally years of low flood in Egypt."

It remains only for us, therefore, to point out that the highest Niles follow the years of the + and − pulses. Thus:—

1871, one year after + pulse 1870.
1876, two years after subsidiary pulse of 1874.
1879, two years after − pulse 1877.
1883-4, one and two years after + pulse 1882.
1893-4, after + pulse 1892 (India excess rainfall, 1892-3-4).

[1] Forecast of S.W. Monsoon rains of 1900.

The Great Indian Famine of 1899.

When, in a sun-spot cycle, the solar temperature is more than usually increased, the regularity of the above effects is liable to be broken, as the advent of the – pulse is retarded.

This, as we have already pointed out, is precisely what happened after the abnormal + heat pulse of 1892, following close upon the condition of solar mean temperature.

The widened line curves, instead of crossing, according to the few precedents we have, in 1897 or 1898, have not crossed yet—that is, the condition of ordinary solar mean temperature has not even yet been reached.

We have shown that, as a matter of fact, in a normal cycle India is supplied from the southern ocean during the minimum sun-spot period, and that this rain is due to some pressure effect brought about in high southern latitudes by the sun at – temperature.

As the – temperature condition was not reached in 1899, as it would have been in a normal year, the rain failed (Fig. 3).

We may say then that the only abnormal famine recorded since 1836 occurred precisely at the time when an abnormal effect of an unprecedented maximum of solar temperature was revealed by the study of the widened lines.

[1] For comparison.

THE BRADFORD MUNICIPAL TECHNICAL COLLEGE.

PROF RÜCKER recently distributed the prizes at the Technical College at Bradford, which was taken over by the municipality a year ago, and is now controlled by a Committee of the City Council. The following is an abstract of his address:—

It would be trite to dwell at length on the changes which have taken place in the educational standards during the last quarter of a century. Then Mr Forster's Education Bill had only been in operation for five years. Now we have free elementary education, and a large sum has been provided for technical education. Two new Universities have been founded and a third, after fifty years' examining, is at length about to teach. Education is not now regarded as the task of a few dons and professors and schoolmasters. It is a matter which the Cabinet discusses, together with the issues of peace and war, and with the federation of daughter States into a Commonwealth. Nay, and in the great spread of local self-government, when Town Councils decide questions which affect more people than constituted, in the beginning of the century, many an independent German State, education is not forgotten; and here in Bradford you have the whole authority and power of your great municipality brought to bear to form a technical school which will support the industries on which your prosperity depends.

And yet, gentlemen, in the midst of all this eager and fruitful effort how difficult it is to decide what the ideal system of education should be. For in any such system two things must be considered, the welfare of the individuals taught and the welfare of the community of which they are a part; and at first sight these two do not always seem to be identical. Each man, the State may say, has a task to perform, which, if he performs it well, is for the good of the community, and, provided he is a good citizen, I care only about his special task. This man may have to dispense justice. My only concern is that he should be a just and learned judge. That man is to be a manufacturer. If he manufactures well, that is all the State need care for. But surely this view only needs stating clearly to show that there must be a fallacy somewhere. Like the old political economy, it assumes that man lives by bread alone. At the best he cannot always be working, and his own happiness—aye, and the good of the State, too—may be affected by whether his amusements are refined or low, upon whether they elevate or debase him. From this point of view the best educators would be insects, which, like ants or bees, have developed special forms of workers, or soldiers, or drones; or even, as is, I believe, the habit of one species, use an individual to store their food till it becomes a mere bloated honey-bag.

Others hold the opposing view. The object of education, they say, is to educate—that is, to bring out the latent capacities of the mind. Provided this end is achieved, it matters little how this is done; but, on the whole, it is better that the subjects taught should be selected rather because they illustrate general principles than because they are likely to be immediately useful. This ideal is to be condemned because it is impracticable for all but the few. It never has been the system adopted for the working man, and has been very imperfectly adopted for the great bulk of the commercial and professional classes. In the stress and struggle of modern life it is becoming more and more difficult to adopt it for anybody, and common sense revolts against the idea that the utility of the subject taught, or of the method of teaching it, is of secondary importance.

We come, then, to the conclusion that the truth lies somewhere between these two extremes, and that the best education is that which will prepare a man for his walk in life, and will also, as far as may be, keep his mind open to interests and ideas other than those upon which his success as a bread-winner directly depends.

I will not attempt, in the short time at my disposal, to sketch out a general system of education in which these conditions would be fulfilled, and, if I did, I should throughout be conscious that I was only throwing an apple of discord among educational experts.

But, taking scientific and technical education as a whole, I am clear that for the better students, at all events, the study of science should be relieved and aided by the study of modern languages.

Nowadays everything is becoming more cosmopolitan. Science is becoming more international. Only this summer I attended the first meeting of a new association of all the great scientific academies of the world. Again, with the new century will begin the publication of an

international catalogue of scientific literature, in which all scientific memoirs and publications will be catalogued.

I quote these instances as they are those which have fallen more immediately under my own observation, but manufacturers can tell a similar tale. The visit of the Iron and Steel Institute and of the Institution of Electrical Engineers to Paris, the visit of the Electrical Engineers to Switzerland, and the travels of the Naval Architects all show that the great professions are becoming more and more international. It is essential that a young man who intends to keep abreast of what is being done abroad should be prepared to read foreign periodicals, and to make the most of any opportunity which may occur of going abroad himself. To do this he must study modern languages. This will be directly useful, and it will also have the great educational advantage that it tends to keep alive an interest in something other than the science or technology to which I am supposing that the attention of the student is chiefly turned.

As matters stand at present, a number of the most intelligent of our youth, after the more elementary parts of their education are completed, devote themselves chiefly to science. Many of the best of them come under my personal observation in the Royal College of Science. Some of them develop such marked scientific ability that they pursue the more theoretical side of their studies, and aim at taking a degree with honours. Their education has often been carried on chiefly by means of State or municipal grants made to the schools or colleges in which they have been educated. In the system of education under which they have been brought up, no effort has been made to induce them to study classics. Yet when they have proved themselves worthy of a high University training in science, they are suddenly stopped in the middle of their career, and told that no further progress towards a degree is possible unless they go back to school again and learn the Latin grammar. I think that the time has come when this should be changed, and a knowledge of modern languages should be allowed to replace Latin.

The hard and fast line of separation which has too often been drawn between the earlier education of those who do and of those who do not propose to go to the University would thus be obliterated. Both should be taught modern languages, both should be taught science, and both would then have acquired a literary and scientific training which could be developed in the further stages of a technical or a University education.

Do not misunderstand me. I am not advocating the abolition of the system of classical education which is predominant in the public schools. But it is too often forgotten that there is another great system of education growing up side by side with that which is based on classics. This system is based on a knowledge of science. The study of classics is introduced into it neither at the beginning as a foundation nor at the end to complete it. It is introduced as a patch in the middle. Of two things one. If Latin is essential, let the State and the municipalities supply funds for it as lavishly as they do for science. If it is not essential, do not insist on introducing it at the most inconvenient moment of the student's career.

But if I would take away something from the burden now laid on beginners, I would also modify the later stages of scientific or technical education.

Up to the present the general training of students of science at the University has ceased with their matriculation. The modicum of Latin which they have then obtained, with a little history and geography, and perhaps some French, is abandoned. The University takes no further note of their progress in these subjects. If I am in favour of ceasing to make Latin compulsory, I also desire that the more advanced students of science or industry should carry on the study of modern languages, which should be regarded as an integral part of a scientific education. Too exclusive attention to one subject would thus be less probable; but nevertheless the student would be directed to what he himself would regard as matter germane to the central interest of his life, for a knowledge of French and German is essential to the proper cultivation of science. These views I have long held, and I am glad to learn that they are very similar to, if not identical with, the views of Lord Rosebery. If the politicians determine on the reform it will become a practical question.

But though anxious that this reform should take place, I am well aware that the matter of immediate, pressing and vital importance for our national welfare is that the knowledge of science should not only be more widely spread among us, but also that the scientific method should be more widely applied to industry.

I have no intention of attempting to read Bradford a lesson on business methods. But you will allow me to congratulate both the scientific and the business worlds on the fact that they are drawing nearer together. A profound knowledge of the secrets of nature may be combined with knowledge of the world, while the business man is often a highly cultivated scholar, and is learning the lesson that he who is quickest to apply new knowledge to old problems is most likely to win and to keep the markets of the world.

Day by day the workshops are growing more and more like scientific laboratories, except that the appliances are on a scale which few laboratories have the means to command. On the other hand, the laboratories are becoming more and more like the homes of scientific industry.

Germany has for some years had a national physical laboratory—the Reichsanstalt—in which scientific questions likely to be useful to industry are investigated. The organisation for which that country is remarkable, and in which we are deficient, was shown by the way in which the scientific exhibits at the Paris Exhibition were dealt with. Those of our scientific instrument makers who sent specimens of their work, each selected and exhibited what seemed to him good. Their exhibits were distinct and separate, and the English exhibit as a whole was a patchwork, with no well-defined scheme or pattern. In Germany the scientific exhibit was supervised by the officials of the Reichsanstalt. Instruments of the same class were exhibited together, whoever their maker might be; and the visitor could see at a glance the best that Germany could produce of each particular type. Assistants were ready to open the cases and to display the wares. Catalogues of the different firms were furnished if the visitor signed a written request, and a central office had been established where orders could be booked. This, of course, was an exceptional piece of work, but the general uses of a national laboratory are permanent; and, owing to the efforts of the British Association and the Royal Society, the Government have lately asked the Royal Society to undertake the management of an institution similar to the Reichsanstalt. The sum granted is very small, as compared with the resources of the German institution, but I do not quarrel with that decision. If the thing is good it will grow, and it is perhaps better not to begin on too large a scale. A year ago we were ready to get to work. Six of the great technical societies are represented on the governing body. Committees have formulated a scheme of work, but grave delay has been occasioned by opposition to the erection of the laboratory at Richmond.

But, gentlemen, putting our difficulties aside, I believe that the foundation of a National Physical Laboratory, and the establishment of a municipal technical school at Bradford are both signs of the growing recognition of the ties between science and industry; and I take it as

another sign of the same fact that the heads of this great technical college have asked me, a student of pure science, to distribute your prizes to-night. I should be misusing the opportunity you have given me if I did not assert the conviction, common both to you and me, that it is by means of the scientific study of various industries, study such as you here carry on, and such as will be carried on in the National Physical Laboratory, that trade and science alike will prosper.

The first nuggets in gold-bearing districts are often picked up upon the surface; but mines can only be worked on a large scale by organised industry. As we penetrate deeper into the secrets of nature, as the industrial struggle grows keener, the rough and ready methods of the past will not win either knowledge or wealth.

We cannot afford to dispense with the old virtues. If we become slack and idle, if we devote to sports, innocent and useful in their place, the energy and attention which others are giving, not to the amusements, but to the business of life, we shall be, as we shall deserve to be, beaten. But to the old virtues we must add new methods, and among these none seems to me more praiseworthy than that a great municipality should determine that the lads who embark on the principle industries of the town shall have an opportunity of mastering the scientific principles on which those industries are based, and shall be shown, as they master them, how the principles are to be applied to the business of life.

THE ALLIANCE BETWEEN SCIENCE AND INDUSTRY.

LAST September Prof. Carhardt communicated to the American Institute of Electrical Engineers a very complete account, which has recently been printed in *Science*, of the Reichsanstalt at Berlin. He had worked there as a guest for some months in 1899, and had thus gained an insight into its management and organisation. The details he gives of these are very interesting, and the proof of the value of the work done, and of its consequences to German industry, most striking. The cost of the Institution, we may note, was about 200,000*l.*; the annual expenditure amounts to about 15,000*l.* After mentioning these figures he continues, "A very pertinent inquiry is, what are the results of all this expenditure?" and a careful analysis leads him to the conclusion that, "The results have already justified, in a remarkable manner, all the expenditure of labour and money. The renown in exact scientific measurements formerly possessed by France and England has now largely been transferred to Germany. Formerly scientific workers in the United States looked to England for exact standards, especially in the department of electricity, now they go to Germany." And again, "Germany is rapidly moving toward industrial supremacy in Europe. One of the most potent factors in this notable advance is the perfected alliance between science and commerce existing in Germany. Science has come to be regarded there as a commercial factor. If England is losing her supremacy in manufactures and in commerce, as many claim, it is because of English conservatism and the failure to utilise to the fullest extent the lessons taught by science."

ANNIVERSARY MEETING OF THE ROYAL SOCIETY.

THE anniversary meeting of the Royal Society was held as usual on St. Andrew's Day, November 30, in the apartments of the Society at Burlington House. The auditors of the treasurer's accounts having read their report, and the secretary having read the list of Fellows elected and deceased since the last anniversary, the president (Lord Lister) proceeded to deliver the anniversary address. After referring to the losses by death sustained by the Society since the previous anniversary, and briefly noticing the work and careers of the deceased Fellows, the president continued his address as follows:—

Through the Malaria Committee the Society has kept in touch with the progress that has been made in unravelling the mystery of the greatest scourge of our tropical colonies, and with the steps that advancing knowledge has suggested for its suppression. The subject has now reached a stage at which it may be not unfitting to refer briefly to what has been accomplished.

The term "malaria" implied the belief that some vitiated state of the atmosphere was the cause of the disease. But the knowledge gained of late years of the parasitic nature of infective disorders pointed clearly to such an origin of the intermittent fevers, as the various manifestations of malaria have been termed. Accordingly diligent and long-continued search was made in the water and the soil of malarious districts in Italy for the suspected living agent, but without success. The discovery was made in 1880 by Laveran, a French army surgeon stationed in Algiers, who observed in the red blood corpuscles of malarious patients what he regarded as adventitious living organisms; not of vegetable nature like the bacteria which constitute the *materies morbi* of so many infective diseases, but a very low form of animal life. In what he believed to be the youngest condition of the organisms, they appeared in the red blood-discs as tiny specks of colourless protoplasm, possessing amœboid movements. These, growing at the expense of the red corpuscles which they inhabited, consumed them more or less completely, at the same time depositing in their own substance a peculiar form of dark brown or black pigment, such as had long been known to form characteristic deposits in the organs of malarious subjects. As they grew they assumed various forms, among which was what Laveran termed the "rosace," a rounded body bearing at its circumference little spherules, while the pigment was accumulated at the centre (*vide* Laveran, Du Paludism, Paris, 1891).

This discovery of Laveran's, at first regarded with the gravest suspicion by pathologists, was the first great step in the etiology of malaria. It supplied the means of distinguishing the disease from its counterfeits, and it explained the wonderful specific efficacy of quinine, till then given only empirically. Quinine is remarkable in the circumstance that it acts with deadly effect upon some microbes, in dilutions which are quite unirritating to the human tissues. It can thus be given in sufficient doses to kill the malaria parasite in the blood without injuring the patient.

Nine years after Laveran's discovery, Golgi, of Pavia, who had been specially studying the "rosace" form of the parasite, and who had become convinced that the spherules at the circumference of the rosace were sporules of the microbe, announced that he had observed differences between the rosaces of the tertian and quartan forms of the fever so great and so constant as to make him satisfied that they were two distinct species of organism. At the same time he had made the extremely important observation that the periods of occurrence of the fever corresponded with the times of maturation of the rosaces. These, all coming to maturity about the same time, shed their sporules into the blood, and this determined the febrile attack. The free sporules then, according to his view, attached themselves severally to other red discs, constituting Laveran's tiny amœbæ, and grew in the red copuscles without causing symptoms till they had produced a fresh crop of sporules ripe for extrusion, the time for this being two days in the tertian and three days in the quartan form. Thus the periodicity of the intermittent fevers and their variety in that respect were alike explained. (*Vide* Laveran, *op. cit.*)

A few months later a third species or the parasite was recognised, having the peculiarity that some of its individuals, instead of being of rounded form, were of crescentic shape. This species received the title æstivo-autumnal, on account of the season in which it showed itself in Italy. It was not so regular in its periods as the others, and was much more dangerous. The existence of these different species was at first very generally doubted, but it is now universally accepted and is of very great importance. The examination of a drop of blood from the finger of the patient enables the physician to decide, not only whether the disease is malaria, but which of the three types it will follow. The more dangerous crescent form is commonest in the tropics, and hence has been termed by Koch

tropical malaria. The quartan has proved the mildest of the three.

The process of sporulation might seem at first sight to explain the whole life-history of the parasites. For their propagation within the human body that process does indeed make ample provision. But the mystery remained—how did they gain entrance into the human system? Though present in abundance in the blood of the malarial patient, they are absent from the excreta. Spontaneous generation having been long since exploded, what could be their mode of origin in the external world? This problem has of late been completely solved.

Among the forms of the parasite observed by Laveran was one which he termed "flagellated," possessing filamentous appendages which exhibited extremely active movements, by virtue of which they were often seen to break off from the parent microbe and swim away. These flagella were regarded by many biologists as products of degeneration resulting from the abnormal influences to which the parasites were exposed in blood outside the body. This Laveran could not believe: indeed, it was the remarkable activity of the flagella that finally satisfied his own mind that what he had discovered were really living parasites: he regarded the flagella as the highest form of development of the microbe. There was another observer who felt equally convinced that the flagella were living elements—our Fellow, Dr. Manson. He, however, went a step further. Seeing that the flagella were never met with in blood when first drawn, but only made their appearance after some little time had elapsed, he conceived that their function must be that of spores for spreading the parasite in the external world, and some suctorial insect seemed to him the probable agency for their diffusion. He had observed several years ago that another parasite of the human blood, a microscopic nematode worm, Filaria, is drawn with the blood into the stomach of a kind of mosquito, and finds in the insect a secondary host, in the tissues of which it passes through a new cycle of development. He became deeply impressed with the idea that a similar series of events might occur with malaria, and he expounded his views fully before the College of Physicians. The notion that mosquitoes might be in some way associated with malaria had occurred to Laveran and to others, but by no one had it been brought home with such logical force as by Manson.

Major Ronald Ross, of the Indian Medical Service, on a visit to this country, became deeply impressed by Manson's arguments, and determined to test his theory on returning to India. Using mosquitoes bred in bottles from the larva, he caused them to bite persons affected with the crescent form of malaria, and afterwards sought in the bodies of the insects for evidence of the development of the parasite within them. For two long years he pursued this search, making about a thousand observations, but to no purpose. So far he had employed two kinds of mosquito common in the district where he was stationed; but in August 1897, having been supplied with some larvæ of a species rare in that locality, and having bred the fully developed insects from them, he induced eight of them to bite a patient with crescents in his blood, and examined their tissues at successive periods. Four of them were killed at once for the investigation of the flagellated bodies. Of the remainder, one examined four days after biting showed, under a high magnifying power, several rounded bodies imbedded in the wall of the stomach, differing from any natural structure of the insect, and containing granules of pigment "identical in appearance to that of the parasite of malaria" (*vide British Medical Journal*, December 18, 1897). The eighth mosquito was killed one day later, and exhibited bodies precisely similar except that they were distinctly larger and more substantial, implying that they had grown in the interval. Thinking that in all probability he had at length found that which he had been so long in search of, and feeling uncertain when he might again obtain the rare species for confirmatory investigation, he at once sent a description of his observations to London, accompanied by his preparations and an independent report upon them by a colleague. Dr. Manson, to whom, among others, they were submitted, was so much struck with the preparations that he had a drawing made of the pigmented bodies in them for publication along with Ross's paper. Though, like Ross, expressing himself with caution, he inclined to his interpretation of the appearances. The paper contained a minute description of the rare mosquito, which seemed to Ross to belong to a "family distinct from the ordinary" kinds.

In the following month he made a similar experiment with another species of mosquito which appeared closely allied to the subject of his last observations. He succeeded, though with some difficulty, in getting two of them to bite a patient with crescents. One of these insects, killed next day, was examined with a negative result; but in the second, killed forty-eight hours after biting, the peculiar pigmented bodies were again seen among the tissues of the stomach. Meanwhile, "some scores" of the species, "unfed or fed on healthy blood, had been examined without finding the cells."

In the same month he observed precisely similar pigmented bodies in a common mosquito which he had seen feeding on a patient affected with the parasite of mild tertian fever. Here he had not the rigorous evidence supplied by insects bred from the larva;[1] and it was quite a new thing to find the pigmented bodies in ordinary mosquitoes. But all the patients on whom his previous observations on the common species had been made had been affected with crescents; and the parasite concerned being in this case a new species, it did not seem unlikely that it might be harboured by the common insects.[2] These new facts removed all doubt from his mind; and he felt that he had the subject in his grasp, and wrote to that effect to Manson. But, to his bitter disappointment, he was at this time despatched to another part of India to study another disease; and thus several precious months were lost.

In February 1898, however, he was told off for the special investigation of malaria, and a laboratory in Calcutta was set apart for his use.[3] Few cases of human malaria being available at that season of the year, he turned his attention to some closely allied forms of disease common in birds. He soon found that one of the ordinary kinds of mosquito, which had invariably given negative results when fed on patients with crescents, developed pigmented bodies among the tissues of the stomach if fed on birds, such as sparrows, containing in their blood the form of bird parasite known as Proteosoma. The birds presented a ready field for experiment; and the kind of mosquito, the grey mosquito as he termed it, was very abundant in Calcutta, so that it was easy for him to hatch from the larva any number that he might require. Discoveries now followed each other in quick succession. He soon announced that the pigmented bodies grew rapidly from day to day, till after about a week they assumed large proportions, projecting like buttons from the outer surface of the stomach, and often showing a curious appearance of radiating striæ. Next we learned that the striæ had been indications of spore formation, and that when the bodies had attained maturity they burst into the general body-cavity, discharging enormous numbers of minute elongated organisms which he termed "germinal rods." Then followed the remarkable observation that the germinal rods soon leave the general body-cavity, and accumulate in the cells of the salivary or poison glands and in the duct leading from them to the proboscis, with which the bites of the insect are inflicted. And, lastly, he completed the cycle of evidence by ascertaining that healthy sparrows could be infected with the Proteosoma by causing mosquitoes to bite them at the appropriate period after biting an infected bird.

Thus was, in truth, established the mosquito theory of malaria. For taking into account the close resemblance of the Proteosoma to the parasites of human malaria, together with the facts ascertained by Ross regarding the infection of the rare mosquitoes with human crescents, we could not doubt that the course of events which he had traced in the sparrow occurred also in man. And the two sets of observations, taken together, clearly established the fact that, as Manson had predicted, different species of malarial parasite may require different kinds of mosquito as their alternative hosts.

At the same time, the presence or absence of the pigmented bodies in the stomach wall afforded a sure means of distinguishing those kinds of mosquitoes which convey malaria to man from those which are incapable of doing so. And it may be added that the multitude of negative results after feeding grey mosquitoes with crescent blood, considering the great prevalence

1 *Vide British Medical Journal* (February 26, 1898). In this second paper Ross did not repeat the description of his method, given in the former article, of using mosquitoes bred in bottles from the larva. But as that had been his practice for more than two years, there can be no reasonable doubt that he continued it with this new species. I have also his personal assurance that such was the case.

2 As the result of further knowledge, there is no doubt that this common mosquito had derived its pigmented bodies, not from the man it was seen biting, but from a bird affected with another species of malarial parasite.

3 It has seemed necessary to refer to these points in detail, as considerable misapprehension has prevailed in some quarters regarding them.

in Indian birds of the parasite with which that species of insect is liable to be infected, afforded pretty conclusive evidence that the mosquito never derives the germs of malaria from the larva and can acquire them only by biting some infected animal.

But although the mosquito theory was thus demonstrated, there remained a link wanting in the chain of biological sequence. The flagella which Manson regarded as spores were destitute of malarial pigment, whereas the smallest corpuscles seen by Ross in the stomach wall invariably possessed it. How was this inconsistency to be explained? What was the relation of the unpigmented flagellum to the pigmented corpuscle? The answer had been already independently supplied.

I was present at a sitting of the Zoological Section of the British Association at the Toronto Meeting in 1897, when Dr. MacCallum, a young pathologist of the Johns Hopkins University at Baltimore, read a paper describing the results of an investigation in which he had long been engaged into another form of malaria parasite, Halteridium, especially common in crows. He told us, and he illustrated his statements with preparations under the microscope, that he had distinguished differences, which he regarded as fundamental, between the spherical bodies seen in the shed blood of a bird affected with that parasite. Though alike in size, some had a more granular protoplasm than the others, which had a more hyaline aspect; and he had observed that the more hyaline ones alone emitted flagella. These, after wriggling themselves free from the parent cell, swam away till they approached some corpuscle of the other, more granular, sort; when the first that reached it plunged into its substance and disappeared, while all others were, by some amazing provision, absolutely refused entrance. Here, then, was witnessed, in an exceedingly low form of animal life, a process of fertilisation identical with that which occurs in an echinus or a fucus. The flagella were neither more nor less than spermatozoa, and the more granular cells were ova. As the result of the fertilisation, the female cell was seen by MacCallum to alter its shape in the shed blood and assume an elongated form to which the term vermiculus was applied. This new creature was possessed of wonderful powers of locomotion, sometimes in its powerful career piercing through the substance of a red corpuscle.[1] Nothing could well be imagined better adapted for penetrating the layer of cells that line the stomach of the mosquito; and as the vermiculus retained its pigment, Ross's pigmented bodies were naturally accounted for.

These observations of MacCallum's might seem at first almost too wonderful for credence; but they have been fully confirmed by others.

It appears to be doubtful whether Halteridium ever produces the "rosace" form, with its attendant sporulation; but there is no doubt that the process of fertilisation seen in that parasite occurs in human malaria. MacCallum himself observed the act of conjugation in the crescentic human form; though he did not see the subsequent development of the vermiculus. Koch made a further step by observing the vermiculus of Proteosoma in blood from the mosquito's stomach.[2] And, finally, our medallist Grassi, who in other ways has made most important contributions to this subject, has, in a recent work (*vide* Grassi, "Studi di uno Zoologo sulla Malaria," Roma, 1900), accompanied by very beautiful illustrations, not only described the presence of vermiculi in abundance in the blood in the stomach of mosquitoes during the first two days after biting patients affected with malaria, but he has traced and figured the pigmented bodies of the smallest size in the tissues of the stomach in the immediately succeeding period, these bodies retaining in some instances the elongated form of the vermiculus after passing through the layer of epithelium that lines the cavity of the organ.

It has thus been abundantly established that the parasites of malaria are present in the patient's blood in two distinct forms, one sporulating asexually in the human system and causing the attacks of fever, the other undergoing sexual development in the body of the mosquito. That both forms are developed from the spores introduced by the mosquito is certain. At what stage they begin to develop their respective peculiarities is not yet quite made out. The crescent form is peculiarly favourable for this inquiry, as it is the crescents only which discharge the sexual function; and they are easily distinguished from the sporulating kind, not only by their shape, but also by their much larger size.

The development of the crescents has been specially studied by the Italian pathologists, Bastianelli and Bignami,[1] who have been able to distinguish the young crescents while still of extremely small dimensions; and they have made the remarkable observation that, while the crescents are as a rule only found in the blood of the finger when they have arrived at maturity, the young forms are to be seen in internal organs, such as the spleen, but above all in the bone marrow, where alone, according to these observers, the youngest recognisable crescents are to be found.

Seeing that, in whatever part of the body they are, the parasites always inhabit the blood, it seems difficult to conceive what can be the cause of their preference, at different stages of their growth, for the blood vessels of different regions and organs. But of this we find parallels in several other cases of blood parasites, the most striking, perhaps, being the astonishing fact that, of two species of Filaria that infest the human blood, one only shows itself in superficial parts at night, and is therefore termed *Filaria nocturna*, while the other has the name *Filaria diurna*, because it only appears by day in the finger blood and retreats into deep parts for the night.

Ross was not an entomologist, and he was unable to learn in India the names of the species of mosquito with which he had been working, till Daniels, one of the explorers sent out by the Malaria Committee, having gone to Calcutta to confirm or otherwise Ross's work, informed him that his rare kinds, which acted as hosts for the human crescents, belonged to the genus Anopheles, and that the common sort which performed the same office for Proteosoma, belonged to another genus, Culex. It has been a matter of great interest to ascertain whether all mosquitoes which act as conveyers of malaria to man are of the genus Anopheles, and the exceedingly common and numerous species of Culex are guiltless in that respect. Very numerous investigations into this question, and especially those conducted by Grassi and his coadjutors, seem to have proved that such is the case, and that, so far as human malaria is concerned, Anopheles alone have to be considered.

Our other two explorers, Messrs. Christophers and Stephens, have made various important contributions to our knowledge of malaria. Thus, having paid special attention to the very dangerous disease which, on account of one of its symptoms, is termed blackwater fever, they have come distinctly to the conclusion that it is not a special disorder but a form of tropical malaria. If this is the case, it is of immense practical importance; for it will follow that any means efficacious for ordinary malaria will prove equally so for the deadly blackwater fever.

Another most important fact which they have ascertained, and which was independently observed by Koch, is that in a native population in a malarious region, while the adults may be perfectly free from the disease, the young children contain the parasites in their blood in an enormously large percentage. Though the disease appears to be much less dangerous to the native children than to new arrivals, implying that they have a degree of congenital immunity, the parasites in the young natives are perfectly efficacious for causing dangerous fever in white people when conveyed to them by mosquitoes. Hence the important practical inference that white people settling in a malarious tropical region should not, as they now commonly do, plant their houses near native settlements, but place them at some considerable distance from them, about a quarter of a mile being apparently sufficient. And Christophers and Stephens in their last communication have gone so far as to express the opinion that the following of this simple rule would go very far indeed towards rendering the malarious tropics healthy to Europeans.

In a communication to this Society, it is the scientific side rather than the practical that is naturally chiefly dwelt on. Yet I should have been glad, had time permitted, to have referred to the various measures of prevention and treatment of malaria which the light of recent knowledge has already suggested, and which have already borne important fruit. I must now content myself with saying that, very various as these measures are, they are all, without exception, based on the mosquito theory.

The medals were then presented as follows :—The Copley Medal to Prof. Marcellin Berthelot, For.Mem.R.S., for his brilliant services to chemical science; the Rumford Medal to Prof. Antoine Henri Becquerel, for his discoveries in radiation proceeding from Uranium; a Royal Medal to Major Percy Alexander MacMahon, F.R.S., for the number and range of his contributions to mathematical science; a Royal Medal to Prof. Alfred Newton, F.R.S., for his eminent contributions to the science of ornithology and the geographical distribution of animals; the Davy Medal to Prof. Guglielmo Koerner, for his brilliant investigations on the position theory of the aromatic compounds; and the Darwin Medal to Prof. Ernst Haeckel, for his long-continued and highly important work in zoology, all of which has been inspired by the spirit of Darwinism.

The Society next proceeded to elect the officers and council for the ensuing year. The following is a list of those elected :—

President: Sir William Huggins, K.C.B.; Treasurer: Mr. A. B. Kempe; Secretaries: Sir Michael Foster, K.C.B., Prof. Arthur William Rücker; Foreign Secretary: Dr T. E. Thorpe; other Members of the Council: Prof. H. E. Armstrong, Mr. C. V. Boys, Dr. Horace T. Brown, Mr. W. H. M. Christie, C.B., Prof. E. B. Elliott, Dr. Hans F. Gadow, Prof. W. M. Hicks, Lord Lister, Prof. W. McIntosh, Dr. Ludwig Mond, Prof. A. W. Reinold, Prof. J. Emerson Reynolds, Dr. R. H. Scott, Prof. C. S. Sherrington, Mr. J. J. H. Teall, Sir J. Wolfe Barry, K.C.B.

In the evening the Fellows and their friends dined together at the Whitehall Rooms.

NOTES.

DR. E. VON MOJSISOVICS, Vice-director of the Austrian Geological Survey, has obtained permission to retire from the active staff of the service on account of the state of his health. But his scientific labours will suffer no interruption. In particular he will be able to continue, and, it may be expected, bring to an early completion, two important works on which he is engaged —"The Cephalopoda of the Halstatt Limestone," and "The Geology of the Salzkammergut."

PROF. J. PERRY, F.R.S., presided at the annual dinner of the Institution of Electrical Engineers on Monday, and in responding to the toast of the Institution he compared the profession of electrical engineering with a baby, inasmuch as the members were ignorant of its future, though they knew that its life would be affected by the action adopted now. Other speakers were Lord Alverstone, Lord Kelvin, Sir J. Wolfe Barry, Sir G. Kitson, and Sir Courtenay Boyle, who spoke as the representative of a department (the Board of Trade) which has to do with the translation of scientific researches into commercial facts.

MR. I. H. BURKILL, of the Royal Botanic Gardens, Kew, has been appointed assistant to Dr. Watt, and will shortly leave for Calcutta.

WE learn from the *Athenaeum* that an official announcement has been made to the effect that the Viennese Akademie der Wissenschaften intends sending an expedition to Brazil in 1901, which will have for its object the study of the flora of that country. It is to a certain extent a sequel of the expeditions of the early part of this century, which resulted in the publication of that monumental work the "Flora Brasiliens." The botanists accompanying the party are Prof. Dr. Richard von Wettstein, Director of the botanical garden of the University, and Dr. Victor Schiffner of Prague.

IT is announced by the Colonial Office that the Pacific Cable Committee have accepted, on behalf of her Majesty's Government and of the Governments of New South Wales, Victoria, Queensland and New Zealand, the tender of the Telegraph Construction and Maintenance Company for the manufacture and laying of the projected Pacific cable. The amount of the tender is 1,795,000*l*., and the work is to be completed by the end of 1902. The cable will run from Vancouver to Queensland and New Zealand, *via* Fanning Island, Fiji and Norfolk Island.

A FEW particulars concerning the Antarctic expedition in course of organisation in Sweden, by Dr. Otto Nordenskjöld, are given in the *Times*. For the purpose of his Antarctic expedition Dr. Nordenskjöld has acquired the steam-whaler the *Antarctic*, which was built for whaling in the Greenland seas by a Norwegian firm, and has performed many voyages in Polar waters. She was eventually acquired by Prof. G. Nathorst, the celebrated geologist and Arctic traveller, who has shared in almost every Swedish Polar expedition. Last year, again, the *Antarctic* was employed in the search for Andrée on the east coast of Greenland, when the owner himself was in command of the expedition, but which yielded no result. The vessel will proceed to Gothenburg for her final equipment. Dr. Nordenskjöld estimates the cost of the expedition at only some 10,000*l*. Of this sum one-half has already been contributed by Swedish subscribers, and King Oscar, with his well-known interest in Swedish explorations, has also promised a considerable amount towards this expedition, the first of its kind ever dispatched from Sweden. Should circumstances permit, the Swedish expedition will, of course, co-operate with the British and German. It is hoped that the *Antarctic* will be ready to sail next August.

THE Lincolnshire Naturalists' Union has recently received several valuable additions to its museum. Further space is required for a large collection of fossils and specimens of rock formation recently presented by Mr. Melville. A large case of drawers containing a number of birds' skins from the collection of the late president of the Union (Mr. John Cordeaux) has been presented by Mrs. Cordeaux. A large collection of fossils and specimens of rock formation has been presented by Mr. A. S. Leslie-Melville. The collections would make a good nucleus for a county museum, and the City Council of Lincoln is to be asked to make suitable provision for them.

IT is satisfactory to know that British engineers and manufacturers are seriously examining the causes which have enabled German and American works to successfully compete with their productions. Sir Lowthian Bell dealt with the subject in his address to the Institution of Junior Engineers on November 30. In the course of his remarks he said: "Some correspondents of our newspapers attributed our loss of ground in the race to ignorance of the scientific truths on which success was dependent; but they could not be aware that at Newcastle, Leeds, Nottingham, Sheffield, Edinburgh and Glasgow there were large and well-appointed colleges for teaching the sciences which for the last twenty-five years had been deemed indispensable in Great Britain for a successful career in metallurgy. Moreover, every ironworks of any importance possessed a suitable laboratory as a guide in its daily operations as well as for original research. Comparison between the United States and England involved two conditions—that imposed by nature, and that resulting from ignorance and consequent want of skill; the former was unavoidable, the other susceptible of remedy. Now, taking the Middlesbrough district in this country and Pittsburg and its vicinity in America, it appeared that the final cost of the minerals, mining and carriage included, consumed for each ton of pig iron at Pittsburg and Middlesbrough was almost identical." Though Sir Lowthian Bell's estimate of the alleged advantages of the Pittsburg works may do something to reassure British manufacturers, his remarks as to educational facilities and industrial research are not so convincing. True, we have our University Colleges and Technical Schools, but in how many districts are they considered by the manufacturers to have

any real connection with industrial progress? When the business man really believes in such institutions, he does not regard them merely as places where a smattering of useful knowledge can be obtained, but as laboratories where adequate provision has to be made for scientific research. As for the laboratories provided for investigation in ironworks and other manufactories, they are as nothing in comparison with what they ought to be. When they do exist, they are often regarded as failures unless every year the cost of their upkeep is less than the saving they effect. What British manufacturers mostly lack is belief in scientific results and sympathy with the scientific spirit. So long as they are deficient in these qualities, they will be unable to derive the fullest advantage from scientific progress.

MR. FOX BOURNE, on behalf of the committee of the Aborigines Protection Society, has addressed a letter to Mr. Chamberlain with reference to the condition of aborigines of Australia. It is submitted that a comprehensive and uniform native policy should be adopted for the whole of Australia, with harmony and equal efficiency in the measures taken for carrying it out. After referring to the importation of Kanaka and other native labour, the letter recognises that arbitrary interference by her Majesty's Goverment would be inexpedient and impracticable, but urges that the Governor-General and his advisers should be communicated with on this subject, in the hope that they will see their way to take such measures as will ensure to the aborigines adequate protection.

MR. A. B. BASSET asked, in our issue of October 11 (p. 572), for a word to designate a non-singular curve, and suggested that a curve having no double points might be termed an "anautotomic curve." Other correspondents have thought that the idea of curves without double points could be conveyed by the words nonsesecting, (p. 7), unautotomic, and nodeless (p. 58). There is an objection to such hybrid terms as "unautotomic," but Mr. W. R. K. Watson writes to point out that "nodeless" stands on different grounds, because the rule against combining elements derived from different languages does not apply to the terminations. Mr. T. B. Sprague also sends us a letter in which he expresses the view that nodeless is a suitable word. Hence, if anautotomic is objected to on the score of euphony, the balance of opinion appears to be in favour of nodeless.

AT a recent meeting of the West Riding section of the Society of Dyers and Colourists, Messrs. A. Dufton and W. M. Gardner read a paper on their arrangement for the production of an artificial light of the same quality as daylight, and illustrated its practical value. The lamp devised for this purpose was shown at the Bradford meeting of the British Association, and has already been briefly described (vol. lxii. p. 563, October 4).

IN *La Nature* of November 24, M. E. Durand-Gréville gives a good description and illustrations of the so-called Pocky or festoon cloud. It was probably first observed by Lamarck about a century ago, and was subsequently frequently seen in the Orkneys, and referred to in pamphlets entitled "Popular weather prognostics of Scotland," by Sir A. Mitchell in 1863, and by the Rev. Dr. Clouston in 1867. It has the appearance of a *cumulus* cloud reversed, or as it would be seen from a balloon, and it was named by the recent International Cloud Committee *mammato-cumulus*. It was supposed to be formed of drops of water, and its occurrence was in most cases followed by storms either of rain or wind. M. Durand's observations lead him to suppose that it is by no means always composed of water-drops, but that it is often formed of small needles of ice. He proposes that this name should be maintained when it is certain that it is composed of water-drops, but to employ the term *mammato-cirrus*, or Poey's *globo-cirrus*, when it is equally clear that the cloud is ormed of ice-crystals.

A REPORT on the acetylene flame, considered with especial reference to its use in physical laboratories, is given by Mr. Edward L. Nichols in the *Journal* of the Franklin Institute. The report deals with the following points: The falling off in illuminating power when the acetylene is stored for some time, especially over water; the influence of the pressure and mode of production; the characteristics of pure acetylene flames; the temperature of the flame; and the uses of acetylene for the lantern, for the production of high temperatures, and for photometric measurements. A further report on the efficiency of the acetylene flame as a source of light is contributed by the same writer to the *Physical Review* (October).

PROF. KLEIN announces that the publication of Gauss's works, which has been delayed since the appearance of the sixth volume, will be resumed under the editorship of Prof. Brendel, who will have the collaboration of Profs. Fricke, Stäckel, Börsch, Krüger and Wiechert. Volume viii. has already appeared, and contains a miscellaneous collection of hitherto unpublished writings on arithmetic, algebra, analysis, probability and geometry. Volume vii. will contain the *Theoria motus*, as well as a complete collection of Gauss's works on astronomical perturbations; volume viii. will deal with Gauss's geodetic operations and certain physical problems, supplementary to those treated in previous volumes; and volume x. will consist of biographical matter, including extracts from Gauss's correspondence.

A DETAILED account of the system of multiplex telegraphy, which has for its basis the use of alternating currents of different frequencies, is given in the *Journal de Physique* for November by M. E. Mercadier.

IN the *Journal de Physique* for November, M. Raphael Dubois describes in a short note some experiments on the use of photobacteria as sources of illumination. By cultures on a large scale, with liquid nutrient media, the author states that it has been possible to illuminate a room with the brilliancy of moonlight.

A COPY of a very rare botanical pamphlet—the "Orbis Eruditi Judicium de Caroli Linnæi, M.D. Scriptis," dated, Holmiæ, 1741, is offered for sale in a German book circular (*Recensions-exemplar*), at the moderate price of 120 marks. This is the only "apology" ever written by "Linnæus, and the only work published by him anonymously. It is especially directed against his bitter antagonist, J. G. Wallerius, the mineralogist. Pritzel, by whom this work was not mentioned in the first edition of his catalogue, states in the second edition that he saw a copy in the library of de Candolle. Besides this only three other copies appear to be known, two of which were offered for sale at an auction in Stockholm in November, 1888. The pamphlet contains a *résumé* of the most important events in the life of Linnæus, as well as a list of his works to date.

IN his presidential address to the twelfth annual meeting of the Association of Economic Entomologists, held in New York last June, Mr. C. P. Gillette urged the importance of the study of the life-histories of insects injurious to crops, saying that much remains to be learned, even in the case of the commonest and most abundant species. The *Proceedings* of the Association are published as a *Bulletin* (No. 26) by the Entomological Division of the U.S. Department of Agriculture. Among the numerous papers, one of the most interesting deals with the methods adopted for the destruction of the green-pea louse, the illustrations showing the extensive scale on which the operations are conducted. The Association, which is stated to be the only one of its kind in existence, comprises 109 members resident in the United States and 42 foreign members.

WE have received a copy of the *Communications* of the Millport marine biological station for November. Among the more important contents are a paper by Miss Newbigin on the

sabellid worms collectively designated as Polychætes, one by Mr. A. Patience on the Decapod Crustacea of the Largs Channel, and one by Mr. J. Rankin on the Tunicates of the Millport neighbourhood, the latter containing descriptions of three new species. Attention may also be directed to a communication by Dr. J. F. Gemmill regarding the influence of nutrition on sex. The mussel and the limpet, in which the differentiation of sex does not take place till a comparatively advanced stage of life, are taken as examples; and it is shown that the more highly nourished individuals living in low zones do not display any preponderance of females over their less fortunate brethren, who are out of water for a longer period at each tide.

PART ii. of vol. xxix. of the *Morphologisches Jahrbuch* is chiefly taken up by investigations on myology, one of these papers, by Herr H. Engert, dealing with the development of the abdominal muscles of birds, while the second, by Herr H. Klaatsch, treats of the short head of the *biceps cruris* (or *femoris*) and the so-called *gracilissimus* muscle of the thigh in mammals. As its subtitle—ein stammesgeschichtlicher Problem—implies, the latter is really a phylogenetic paper, taking into consideration the relations of man to the other Primates, and of the latter to other mammalian orders. To formulate the author's investigations and conclusions briefly is by no means easy. But it may be mentioned that he identifies the *gracilissimus* (which must not be confused with the *gracilis*) with the short head of the *biceps cruris* of human anatomy, and finds that the lower Old World monkeys possess no representative of this muscle at all. For this muscle, in its different forms, the name *gluteo-cruralis* is proposed. It occurs as a true *gracilissimus* in the lower American monkeys, all Carnivora, and certain Rodents, Marsupials, Edentates and Insectivora. As the main muscle of the upper leg it is found in some Edentates, the Orang, and the majority of the American monkeys, while it forms the short head of the *biceps cruris* in man, Gibbons, the Howlers, the Chimpanzee and the Gorilla. Whether the Old World monkeys have lost the *gracilissimus*, or whether they never possessed that muscle, is left an open question. But it is urged that the less a monkey departs from the primitive type (as represented by the Carnivora), the nearer it approaches man, and in this respect the majority of American monkeys are more man-like than their Old World representatives.

To the *Zeitschrift fur wissenschaftliche Zoologie* (vol. xviii., pt. 3), Herr C. Sihler contributes a paper on muscle-nerves, while in the same issue Herr R. Hesse continues his investigations on the visual organs of the lower animals, dealing in this instance with the eyes of certain molluscs.

MR. THOMAS SHEPPARD has prepared a descriptive catalogue of the specimens in the Mortimer Museum of Archæology and Geology at Driffield. The specimens were gathered together by Mr. J. R. Mortimer during the past forty years, and they comprise relics of Neolithic and later periods which are described, explained and in many cases illustrated in the work before us. Some doubtful Palæolithic and Eolithic flints are mentioned. Mr. Mortimer began collecting at a time when the Yorkshire Wolds formed a region prolific in pre-historic remains. The farm labourers were induced to spend their spare time in searching for them, and many a basketful of specimens was brought to Mr. Mortimer. Now these treasures are rare. Fossils from the chalk were also more readily to be obtained in former years, when the chalk was more extensively quarried, and a fine series of fossils from this and other local strata is exhibited in the museum. The handbook now issued will be of essential service to local workers.

FURTHER illustrations are presented by Mr. W. J. G. Land, in a short article reprinted from the *Botanical Gazette*, of the remarkable process in the fertilisation of flowering plants observed by Nawaschin, Guignard, Miss Sargant, and others. These observations explain the invariable presence of two sperm-nuclei in the pollen-tube by the fact that, while one of them fuses with the oosphere to produce the embryo, the other fuses with one of the polar nuclei of the embryo-sac (or with both when combined into the central nucleus) to produce the endosperm. Mr. Land adds to the Angiosperms in which this process has been observed two genera of Compositæ, *Erigeron* and *Silphium*. He does not accept Guignard's designation of the process "pseudo-fecundation," but regards it as a true process of impregnation. It is interesting, also, to note that in these genera the sperm-nuclei of the pollen-tube have, as in other instances, the coiled form, which indicates their descent from the spermatozoids of vascular cryptogams.

THE *Agricultural Gazette* of New South Wales contains an article by Mr. W. J. Allen on the culture of the olive in Australia. He states that in both South Australia and Victoria this industry has received considerable attention, good crops of fruit being now obtained which yield a good oil. It is evident, however, that if, as Mr. Allen says, the climate of every part of New South Wales is suitable for the growth of the olive, it may in the future become a much more important industry in our Australian colonies than it is at present.

THE December number of the *Journal* of the Chemical Society contains a portrait of the late Prof. Nilson, and the Nilson memorial lecture delivered by Prof. O. Pettersson.

MESSRS. BLACKIE AND SON have published the seventh edition of "An Elementary Text-book of Coal Mining," by Mr. Robert Peel. A chapter has been added on the applications of electricity to various operations in mining.

MR. A. M. BRICE gives a graphic account of the great Charleston earthquake of 1886, in the December number of *Macmillan's Magazine*. In many respects it resembles Mr. McKinley's equally vivid account quoted in Captain Dutton's memoir. The panic of the whites, the childish terror of the negroes, the destruction of the city and many other features are well described. Mr. Brice also gives some interesting examples of the apparently capricious effects of the earthquake, some houses being comparatively unhurt and yet standing in the midst of others completely ruined.

THE *Transactions* of the Rochdale Literary and Scientific Society contain papers on various subjects read before that Society. In vol. vi. (1898–1900), among the articles of general scientific interest are a list of the birds that frequent Hollingworth Lake, by Mr. J. Stott, and a description of Hades Hill Barrow, by Mr. W. H. Sutcliffe. This is a round barrow and contained a broken rude urn, some burnt bones and flint implements and flakes.

IN NATURE (vol. liv. pp. 449–450), an account is given of the sea-waves connected with the Japanese earthquake of June 15, 1896, so far as they affected the eastern coasts of the islands. The propagation of the sea-waves across the Pacific is discussed by Dr. C. Davison in the last number of the *Philosophical Magazine*. Copies of the records of the tide-gauges at Honolulu and Sausalito (San Francisco Bay) are given. The earthquake originated beneath an area near the foot of the western slope of the Tuscarora Deep, and the sea-waves traversed the distances from the epicentre to Honolulu and Sausalito, which are 3591 and 4787 miles, in 7h. 44m. and 10h. 34m. respectively. The path from the epicentre to Sausalito is free from islands, and the mean depth along it is roughly 17,000 feet. If the depth were uniform, that corresponding to the mean velocity with which the waves travelled would be 13,778 feet. The explanation of the

discrepancy is given by the same writer in a former paper (*Phil. Mag.* for January 1897), in which it is shown that the formula generally used for determining the mean depth of the ocean is incorrectly applied.

An interesting account of an old Indian settlement in Kansas is given by Mr. J. A. Udden in the second number of the Augustana Library Publications, Ill. The paper is well illustrated by a number of excellent figures, and it gives an instructive view of the culture of a frontier village, which exhibits a mingling of northern, southern and western features of primitive industry and art.

In a short essay on Tabu in *l'Anthropologie* (Tome xi., p. 401), M. Salomon Reinach points out that the primitive idea of Tabu is more restricted than mere prohibition. It has three characteristics: (1) no reason is assigned, but reasons are added later; (2) the punishment, whether of death or sickness, results automatically from the infringement. Neither a deity nor man, individual or collective, is credited with avenging power; (3) the danger is not apparent. The power of Tabu has been broken by various religions, who have in their turn at times been sad enemies to human liberty.

Naturalists and others interested in bird life will be pleased to learn that arrangements have been made for the speedy resumption of the publication of Mr. W. Eagle Clarke's work on the birds of Yorkshire, which has been partly published in the *Transactions* of the Yorkshire Naturalists' Union, and the continuation of which was interrupted by Mr. Clarke's leaving Yorkshire to settle in Edinburgh. Mr. Thos. H. Nelson, of Redcar, will continue and complete the work. He has now in his possession the original and unpublished observations which Mr. Clarke had at his command when writing the instalments which are already in print, and which include notes, lists and observations from most of the naturalists who have studied and observed Yorkshire birds. In addition to this is the whole of the information amassed by the late Mr. John Cordeaux relating to the birds of the Humber district, and also the notes which Mr. W. Denison Roebuck has extracted from the very voluminous literature of the subject, and Mr. Nelson's own accumulated series of notes on the birds of Cleveland and other districts, the whole forming an ample mass of material for the purpose.

Mr. Walter W. Froggatt, the Government entomologist of New South Wales, has lately published a series of rather important papers, chiefly as "Miscellaneous Publications" of the Department of Agriculture at Sydney. Among those issued during the present year are No. 358, "Notes on Australian Coccidæ (Scale Insects)"; No. 363, "Plague Locusts"; No. 363, "The Hessian Fly (*Cecidomyia destructor*, Say) and allied Grain Pests"; No. 387, "Insects and Birds"; No. 388, "Insects living in Figs, with some account of Caprification." Other papers by Mr. Froggatt before us are "Miscellaneous Publication," No. 394, "Notes on a Collection of Ticks, determined by Prof. Neumann," from the *Agricultural Gazette* of N. S. Wales; "Scale Insects that produce Lac, with a description of a new Australian Species"; apparently an independently issued pamphlet; and "Australian Psyllidæ," from the *Proceedings* of the Linnean Society of New South Wales, for May. The last paper is illustrated with four plates, and most of the others with one each.

The question of the possible variability of the valency of carbon has received a considerable amount of attention, especially since the researches of Nef on divalent carbon. In the current number of the *Berichte* there is a somewhat startling extension of this idea by Mr. M. Gomberg. By the action of metals such as silver, zinc and mercury upon triphenyl-chlormethane, $(C_6H_5)_3CCl$, the halogen is removed, and, working in the complete absence of air, the resulting product is not as would be expected hexaphenyl-ethane, but an unsaturated body which readily absorbs oxygen from the air and combines directly with the halogens. The author thinks that the only possible explanation of the observed facts lies in the assumption that the substance is really triphenyl-methyl, $(C_6H_5)_3C$, in which the carbon is trivalent. Further work on this subject will be awaited with interest.

The additions to the Zoological Society's Gardens during the past week include a Suricate (*Suricata tetradactyla*) from South Africa, presented by Captain J. C. Brinton; a Raven (*Corvus corax*), British, presented by Mr. J. C. Brush; four Ashy-crowned Finch Larks (*Pyrrhulauda grisea*), two Singing Bush Larks (*Mirafra cantillans*), two Slaty-headed Parrakeets (*Palaeornis schisticeps*), a Golden-eyed Fruit Pigeon (*Carpophaga concinna*) from British India, a Burmese Slaty-headed Parrakeet (*Palaeornis finchi*) from Burmah, presented by Mr. E. W. Harper; a Doguera Baboon (*Cynocephalus doguera*, ♂) from Abyssinia, a Salvin's Amazon (*Chrysotis salvini*) from South America, three Alligator Terrapins (*Chelydra serpentina*), two Sculptured Terrapins (*Clemmys insculpta*), three Blue Lizards (*Gerrhonotus caeruleus*), two King Snakes (*Coronella getulus*), a Three-striped Boa (*Lichanura trivigata*), six American Box Tortoises (*Cistudo carolina*) from North America, twenty Climbing Anabas (*Anabas scandens*) from India, deposited.

OUR ASTRONOMICAL COLUMN.

Perturbations of Eros Produced by Mars.—H. N. Russell has recently published the results of an extensive investigation of the perturbations of the major axis of the orbit of Eros by the action of Mars in the *Astronomical Journal* (vol. xxi. No. 484). As the periods of the two planets are nearly equal and their orbits interlock, the disturbing force will in consequence vary greatly in magnitude, and may have any direction whatever. Also, as Eros is sometimes nearer the sun than Mars, and sometimes more remote, the development of the perturbative function proceeding by powers of the ratio of their radii vectores gives rise to a *divergent* series; and as the magnitude of the eccentricities and inclinations makes development in ascending powers of these quantities undesirable, methods based upon mechanical quadrature are preferable.

The present investigation has been by means of Le Verrier's method of interpolation, and its relative merits and disadvantages are discussed. Newcomb's Elements of Mars have been used, those of Eros being original computations published in the *Astronomical Journal* (No. 473).

The numerical results obtained are given in a table, the chief results being:—

(1) The "great inequality," of period about 1000 years, will not affect the place of Eros sensibly during the next dozen years.

(2) The perturbations of moderately long period are much the largest produced by Mars on any planet. They may displace Eros by as much as 90″ in mean longitude; and since at a perihelion-opposition any change in the mean longitude of Eros produces one *ten* times as great in its geocentric longitude, the measurement of this displacement will eventually lead to a valuable determination of the mass of Mars.

Catalogue of One Hundred New Double Stars.—Prof. W. J. Hussey, of the Lick Observatory, has completed observations of another hundred new pairs in continuation of those in his first catalogue, published in the *Astronomical Journal* (No. 480), and gives the details of the recent measures in No. 485. The work has been done with the 12- and 36-inch equatorials, chiefly with the latter, using generally a power of 1000. An analysis of the distances between the components leads to the following summary:—

Distance.	No. of Pairs.
0″·25 or less	9
0″·26 to 0″·50	16
0″·51 to 1″·00	22
1″·01 to 2″·00	26
2″·01 to 5″·00	27

OSCILLOGRAPHS.

THE phenomena connected with the behaviour of alternating currents present a wide field for experimental inquiry which has, up to the present, been but imperfectly explored. The investigation of the wave-forms of alternating potential differences and currents under various conditions of their actual use is a matter, not only of great theoretical and scientific interest, but also of the highest practical importance, since the shape of the wave-form under given conditions, and the alteration of shape produced by any alteration of conditions, are factors which largely affect the efficiency and economy of working. As examples showing the increased efficiency that may be obtained by choosing a suitable wave-form, we may quote the results obtained by Messrs. Rössler and Wedding, and by Messrs. Barr, Beeton and Taylor. The former experimenters showed,[1] in an investigation on the luminous efficiency of the alternate current arc, that the light per watt when using an alternator giving a flat-topped E.M.F. curve was 44 per cent. higher than when using a machine that gave a peaked curve. Messrs. Barr, Beeton and Taylor, in a research on the efficiency of transformers, found,[2] on the contrary, that a peaked wave-form was the most suitable one to employ. The reactions that take place between alternators running in parallel is another case in which the wave-form is of very great practical importance.

It will be readily understood, therefore, that it is most desirable that we should have some simple method of observing and studying the wave-form of an alternating current or potential difference. Such a method is supplied by the instruments known as oscillographs. Before the invention of these instruments the only means of studying wave-forms was by the exceedingly laborious "point-to-point" method. Suppose that there is a circuit through which is flowing an electric current which is varying periodically at the rate of, say, n, complete cycles per second, and that it is desired to obtain the wave-form of this current. At any particular instant the current will have a certain definite magnitude and direction, and $1/n$th of a second later the current will again have the same magnitude and direction. If, by means of an automatic contact-maker, a galvanometer is brought into circuit at intervals of $1/n$th of a second, there will be given to the galvanometer needle a succession of impulses due, in each case, to the same current, and consequently a steady deflection of the needle will be produced from which the particular instantaneous value of the current can be determined. To obtain, however, the complete wave-form, we must determine the value of the instantaneous current at *every moment* during the cycle, or at a sufficient number of moments to enable a smooth curve to be drawn. Having found one point on the wave-form in the way described, the contact-maker is shifted so as to bring the galvanometer periodically into circuit at some other moment in the cycle, and a second point on the curve is then found. Again the contact-maker is shifted and a third point is obtained, and thus, point by point, the whole curve may be built up.

This method is open to two objections. In the first place, it is only applicable to cases in which the wave-form is undoubtedly steady, all transient effects being obviously unobservable by such a process, and, secondly, it is so lengthy that elaborate researches are practically precluded. As much as four or five hours may, indeed, be spent in obtaining a single curve, and then, even after all this labour, it is more than possible that the conditions will be found to have altered during the experiment, and the curve, in consequence, to be useless. By means of the oscillograph and kindred instruments, however, experiments can now be carried out in a few minutes which occupied days by the old "point-to-point" method, and not only can steady wave-forms be examined, but the most fleeting effects can be studied with equal ease.

An oscillograph may be defined as a galvanometer the deflection of which, at any instant, is practically proportional to the current flowing through it at that instant, in spite of the current varying very rapidly in strength or in direction. For this to be possible it is necessary for the free periodic time of the moving part of the instrument to be very short, less, generally, than 1/30th, of the periodic time of the effect to be observed. The instrument must also be perfectly dead-beat, the moving part taking up instantaneously the deflection proper to the current flowing through the instrument, for if there be any tendency to overshoot the mark it will cause the observed wave-form to be distorted from its true shape. In addition to this, since one is dealing with rapidly varying currents, it is necessary for the self-induction of the instrument to be practically nil, and for all effects due to hysteresis or eddy-currents to be eliminated. The original idea of the oscillograph is due to M. Blondel, who pointed out, in 1893, the principles on which such an instrument should be designed, and all the oscillographs since produced owe their inspiration to M. Blondel's work.

Two other instruments have been invented and developed by which the same end might be attained, namely, the observation or recording of rapidly varying currents or potential differences. These are the Abraham-Carpentier rheograph and the Hess-Braun oscillo-radiograph. With these instruments, since they are not, strictly speaking, oscillographs, we do not propose to deal in detail, but must content ourselves by giving a brief account of the principles on which they are constructed. In the rheograph, instead of making the free periodic time of the instrument excessively small, M. Abraham uses a galvanometer with a period of about 1/10th of a second, and attempts to compensate errors due to the inertia of the moving part by utilising the effects of electromagnetic induction. With this instrument M. Abraham, it is said, has been able to study oscillating discharges having a period of about 1/10,000th of a second; but the adjustment is not an easy matter, and, moreover, has to be made every time the instrument is used. In the Hess-Braun oscillo-radiograph the difficulty of

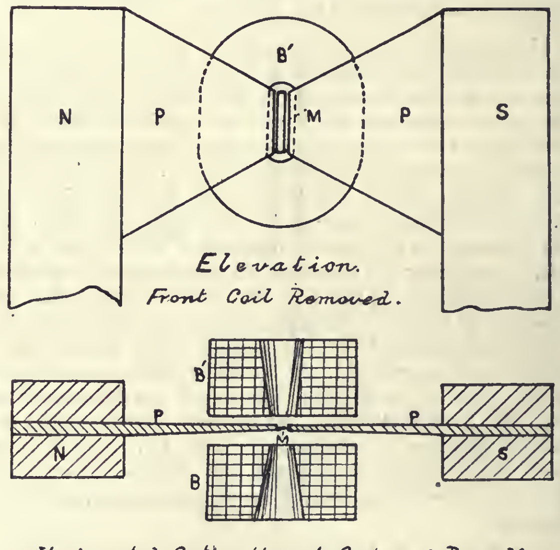

FIG. 1.—M. Blondel's oscillograph.

sufficiently reducing the inertia of the moving part is overcome in a very ingenious manner by using, as the galvanometer "needle," a beam of kathode rays in a vacuum tube. This beam is arranged to produce a bright spot on a fluorescent screen, and the movements of this spot are observed when the beam is deflected by the varying currents passing through two bobbins of wire on either side of the vacuum tube. Unfortunately these bobbins, possessing self-induction, introduce errors. Another difficulty in this apparatus is to obtain good definition, and also sufficient intensity of illumination. On account of the small intensity it is only possible to use this instrument for the study of cyclic phenomena where, as the spot of light can be caused to travel over the same curve again and again, the curve can be observed or photographed.

Neither of these instruments has been brought to the same degree of perfection as the oscillograph, which has been developed into a very perfect instrument by M. Blondel in France and by Mr. Duddell in England. M. Blondel originally suggested three systems on which oscillographs might be constructed, in which the moving part consisted respectively of a small bar of soft iron, a vibrating plate of iron, and a light coil on a bifilar suspension. The instrument which M. Blondel first perfected, and with which his well known researches on the alternate current arc were carried out, was constructed on the first of these systems. The diagram (Fig. 1) shows the chief principles of its construc-

[1] *The Electrician*, 1894, vol. xxxiii.
[2] *Journal* of the Institution of Electrical Engineers, 1896, vol. xxv.

tion. A small bar of soft iron, M, to which is attached a light mirror, is pivoted between the pole-pieces, P.P., of a powerful magnet or electro-magnet. These pole-pieces are laminated and are specially shaped to give as strong a magnetic field in the air gap as possible. On each side of the pole-pieces is a coil of wire, B.B., through which the current to be observed flows. This current produces a field at right angles to that of the field magnet, and so deflects the iron bar through an angle which, if small, is proportional to the current. M. Blondel has produced an instrument of this type having a free periodic time of 1/6000th of a second; and, by replacing the small bar with an iron band stretched between the pole pieces, he has constructed an instrument having much smaller free periodic time than any other type of oscillograph—indeed as small as 1/50,000th of a second—but the sensibility at this high frequency is not very great. At a frequency of about 10,000 vibrations per second, its sensibility is about the same as that of the other types of instrument.

The credit of developing the bifilar oscillograph is due to Mr. Duddell, who, as the result of a long series of investigations

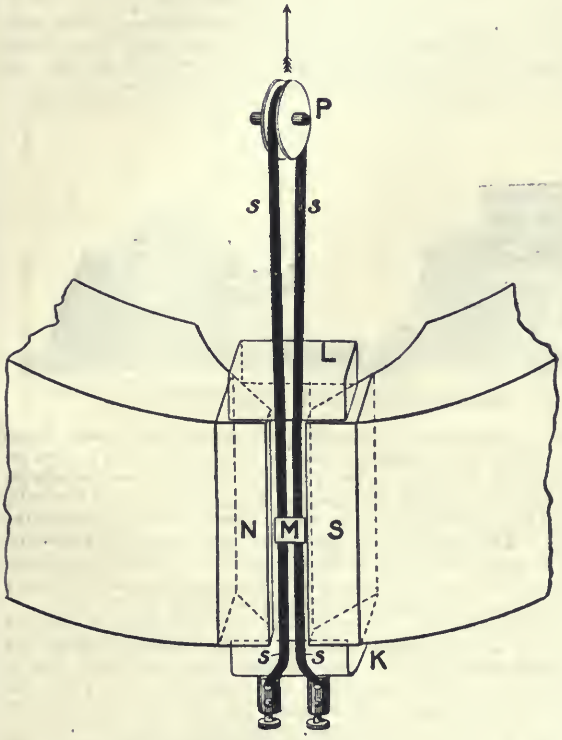

FIG. 2.—Mr. Duddell's oscillograph. (From the *Journal* of the Inst. Elect. Eng., vol. xxviii., 1899, p. 8.)

carried out at the Central Technical College, has produced instruments of this type possessing a high degree of perfection, and by means of their use has brought to light a number of new experimental facts. The principle of Mr. Duddell's oscillograph will be easily understood by reference to Fig. 2. The current to be observed flows up one side and down the other of the continuous strip of phosphor-bronze, *s.s.s.s.* This strip is looped over the pulley, P, which is attached to a small spring balance (see Fig. 3) by means of which the tension on the strip can be regulated. Each arm of the loop passes through the gap between the poles, N.S., of a powerful electro-magnet. The loop carries at its centre a mirror, M, which is made of a small piece of silvered cover-glass cemented to the strips. When a current passes through the loop, one side is moved forward and the other backward, and the mirror is thus deflected through an angle proportional to the current. The phosphor-bronze strips are held in position at the bottom by being clamped between ebonite insulating pieces at K, and at the top by being drawn against the single ebonite piece at L. It will be observed, therefore, that the only part of the strip that takes part in the vibration is that between K and L, and not, as might otherwise be supposed, the whole length from K to the pulley P.

By the use of phosphor-bronze, Mr. Duddell has found it possible to make very light strips having sufficient strength to enable considerable tension to be used, and having, at the same time, good conductivity. He has been able to bring down the free periodic time to 1/10,000th of a second, and, with a free periodic time as low as this, the mirror can easily follow, with extreme accuracy, the vibrations of an electric current alternating at the rate of 300 complete cycles per second, while even if the alternating current has a periodic time as short as 0·001 second, or even less, the record may possess sufficient accuracy for many purposes. The narrow gap through which the strips pass is only just large enough to allow of their free movement, and as the break in the magnetic circuit is consequently very small, the field can be made very intense. This space is filled with damping-oil, which is retained in it by a lens forming a front to the gap, and thus the strips are confined in a narrow oil-bath, in which they have only just room to move, the damping in consequence being very efficient and rendering the instrument accurately dead-beat.

Already the Cambridge Scientific Instrument Co. have constructed many specimens of two types of this form of oscillograph,

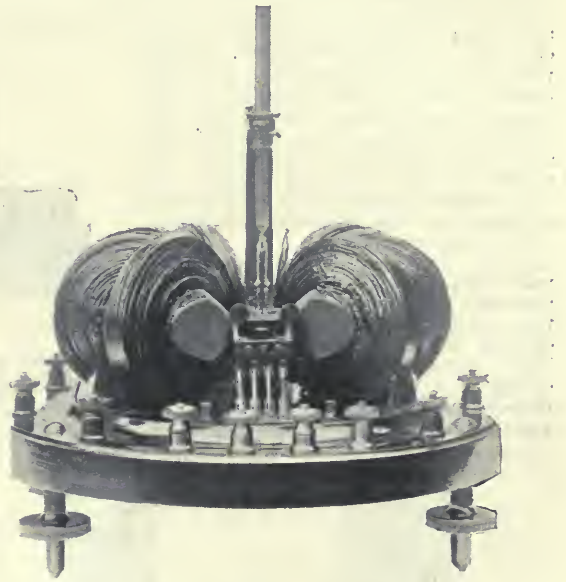

FIG. 3.—Mr. Duddell's oscillograph. High frequency pattern.

a large one for projection work and a high frequency instrument for more accurate research work. The general design in both types is the same, the chief difference lying in the high frequency pattern having its moving parts smaller and lighter, by which means the periodic time of 1/10,000th second has been obtained, whereas the free periodic time of the projection instrument is 1/2000th of a second. The instrument is made with two loops fixed side by side in the gap so that one may be used to give the wave-form of the current while the other is used to give the wave-form of the potential difference, the two curves being thus obtained simultaneously. There is a third fixed mirror between the two vibrating mirrors which is used to give a zero line. Small tangent screws enable the positions of the moving mirrors to be adjusted to zero. From Fig. 3, which is a photograph of the double instrument, a good idea of its general appearance and construction may be obtained. The light band between the poles of the magnet shows the position of the mirrors, but the illustration is on too small a scale for the mirrors themselves to be distinctly visible. This is not surprising when one considers that their actual size is only 1·0 mm. high by 0·3 mm. wide by about 0·1 mm. thick. The strips are connected through the four small upright fuses with the terminals on the front of the base of the instrument. The normal working current in the strips is 0·10 amp., and the sensibility at a scale distance

of 1000 mm. is nearly 600 mm. per ampere. The other terminals which are seen make connection with the magnet, on which there are four pairs of coils the ends of which are brought out to separate terminals so that the coils may be connected up

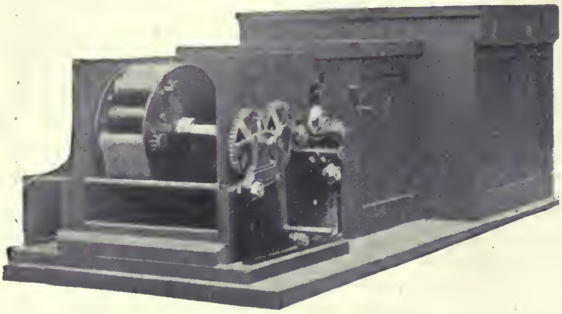

FIG. 4.—Photographic recording arrangement.

in series or parallel to suit the voltage obtainable. The magnet is wound so that the coils may be connected in series direct across 100 volt mains.

It is interesting to note that the oscillograph may be used to show the power curves, as well as the curves of current and potential difference. For this purpose it is only necessary to excite the electro-magnet by the alternating current, instead of from a direct current supply, when the instrument will act as a watt-meter, and give the power-curves. The accuracy is not so high when the oscillograph is used in this way; but the possibility of so using it is very advantageous, both for purposes of demonstration and research.

In order to observe the actual shape of the wave-form, it is necessary to introduce a movement of the beam of light reflected from the oscillograph mirror at right angles to the direction of vibration it already possesses. This may be done by observing the movements of the spot of light in a rotating mirror, or, if permanent records are desired, by receiving the spot on a moving photographic plate or film. This method may be used for observing or

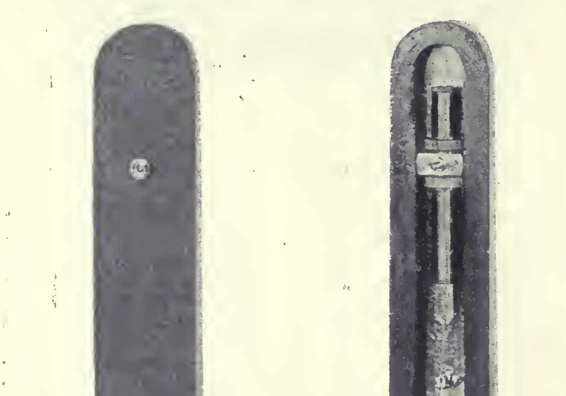

FIG. 6.—Mr. Duddell's portable pattern oscillograph.

recording any variations in current, whether they be periodic or not. In Fig. 4 is shown a photograph of the recording arrangement. The oscillograph is in the back part of the box, and in the front part may be seen the recording drum, which carries Kodak daylight changing spools. There is a shutter between the oscillograph and the film which enables any length of film up to 40 cm. to be used at each experiment, and this shutter carries a contact maker which can be used to start any non-periodic phenomena it may be desired to record. For the cases in which it is only periodic changes which have to be studied, Mr. Duddell has devised a very convenient arrangement in which the rotating mirror is replaced by one which is vibrated in synchronism with the waves of potential difference or current under observation. The mirror is vibrated by a small synchronous motor, and the spot of light is reflected from it on to a transparent screen above it; as the mirror moves with a uniformly increasing displacement the wave form is drawn on this screen, and when arrived at the full extent of its motion, the mirror is pressed back suddenly to its initial position, the beam of light being interrupted during this return journey by a shutter attached to the motor shaft. The mirror then starts on a fresh swing, and draws a second wave-form on the top of the first, the successive curves appearing, by persistence of vision, on the screen as a single bright line, which may be either traced, or photographed on sensitive paper. The size of the curves is about 3 cm. amplitude on each side of the zero and about 8 cm. in length, one and a half complete wave-forms being shown in this length. Fig 5 shows the synchronous motor in conjunction with the large oscillograph, the photograph illustrating the complete apparatus for projecting the curves on to a wall screen. On the right is the source of light, and the oscillograph is on the extreme

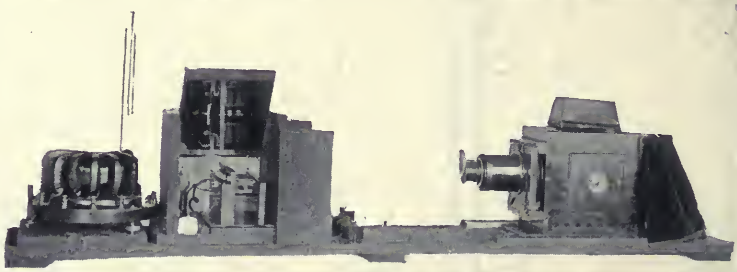

FIG. 5.—Arrangement of apparatus for projection work.

left; to the right of the oscillograph is the motor which drives the synchronous mirror, a view of the top of which is seen reflected in the glass above, this additional mirror being simply introduced to reflect the beam of light, which comes vertically from the synchronous mirror on the motor, horizontally on to the wall. The apparatus will give wave-forms having an amplitude of 50 cm. on either side of the zero and about 150 cm. long, showing in this length one and a half wave-lengths, and sufficiently bright to be seen by over two hundred people at one time.

Mr. Duddell has, we understand, just completed a portable form of oscillograph in which the electro-magnet is replaced by a permanent magnet. This instrument has only one loop of strip, so that it will only show one curve at a time; the free periodic time is 1/5000 of a second, and the sensibility at 1000 mm. scale distance is 750 mm. per ampere. Fig. 6 is a photograph of this small oscillograph, and shows the instrument with and without the front which protects all the working parts. The whole apparatus for observing wave-forms—oscillograph, source of light and rotating mirror—is fitted up ready for use in a small and easily portable box, and should prove of great value to central station engineers and others who employ alternating currents.

In Fig. 7 are shown some examples of curves of current and potential difference obtained by means of the oscillograph. These curves were photographed on to a falling plate, and are here reproduced half full size. Curve 1 shows the wave-forms of the P.D. between the terminals of a dynamo sending a current through an inductive and non-inductive resistance in series, and of the P.D. between the terminals of the non-inductive part, as well as the wave-form of the current flowing in the circuit. It will be seen that the self-induction has caused the current curve to be out of phase with the dynamo P.D., but there is no distortion of the shape. Curve 2 shows the characteristic wave-forms of the current and P.D. of an alternating current arc, burning between solid carbons. The P.D. has a high peak at the beginning, and the current curve lies flat along the zero line at the beginning and end of each half-wave. Curve 3 is for an arc burning between carbon

and zinc; these waves are particularly interesting, as it would be practically impossible to obtain them by the "point-to-point" method, since arcs between carbon and metals burn very unsteadily. The arc, it will be seen, only burns for half a period; when the metal is positive (upper curves) the current is able to flow, and the P.D. and current curves have the shape characteristic of the same curves for the carbon arc, only somewhat accentuated; for the other half period, when the metal is negative no current flows at all, and the current curve is flat along the zero line, the P.D. curve being, in consequence, that given by the dynamo on open circuit. The three curves are for a frequency of 100 periods per second. Curve 4 shows the P.D. and current through the primary of an induction coil in which the contact-maker was driven by a motor, no condenser being used. The steady growth of the current and its rapid fall at break can be clearly observed in the current curve. From the P.D. curve it will be seen that the P.D. at the start is high, since, until the current begins to flow, the P.D. between

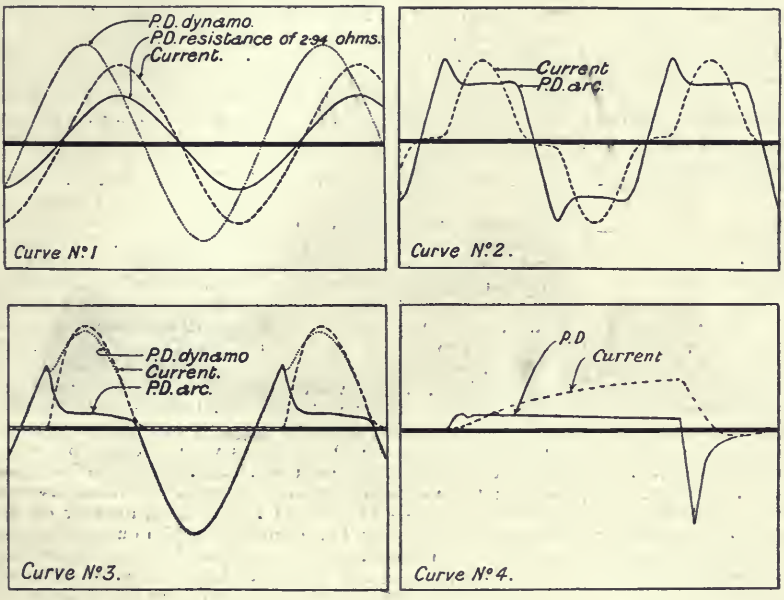

FIG. 7.

Data for Curves in Fig. 7.

No. of Curve.	Wave Forms for.	Periods per second.	Scale of P.D. Curve.	Scale of Current Curve.
1	Non-inductive Resistance.	100	1 mm. = 10 volts.	1 mm. = 2 amps.
2	Solid Carbon Arc.	100	1 mm. = 6 volts.	1 mm. = 2 amps.
3	Zinc-Carbon Arc.	100	1 mm. = 10 volts.	1 mm. = 2 amps.
4	Primary of an Induction Coil.	60 breaks	1 mm. = 2 volts.	1 mm. = 1 amp.

the terminals of the coil is equal to the E.M.F. of the cells. As the current rises, the P.D. between the terminals of the coil falls, due to the drop in volts in the circuit outside the coil; finally the break occurs and there is a large kick of the P.D. in the opposite direction to that applied.

From what has been said some idea will be gathered of the great value of the instrument that has been put into our hands by the invention of the oscillograph. To the scientific investigator it opens wide fields for experimental research, and it will enable the engineer to know more about the currents and E.M.F.'s with which he works. In addition, the projection oscillograph should prove invaluable for lecture and demonstration purposes, for even the simplest problems of alternate current working are by no means easy of comprehension by the average electrical student, who approaches them with only a bowing acquaintance with differential calculus and Fourier's theorem. The remarkable clearness with which their working can be demonstrated on the screen by the oscillograph will go a long way to give students a clear idea of their properties.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Mr. T. Loveday, of Magdalen College, has been elected John Locke Scholar for the ensuing year.

Mr. G. C. Bourne has been re appointed a delegate for the extension of University teaching.

The electors to the Wykeham Professorship of Physics have appointed Mr. J. S. Townsend, Fellow of Trinity College, Cambridge, and Demonstrator in the Cavendish Laboratory.

CAMBRIDGE.—The Clerk Maxwell Scholarship in physics is vacant through the election of Mr. J. S. Townsend to a professorship at Oxford. Candidates are to apply to Prof. J. J. Thomson by December 18.

The British Westinghouse Electric Company have presented to the Engineering Laboratory a valuable dynamo and other apparatus illustrating the generation and use of polyphase currents.

AN opportunity for seeing the Northampton Institute, Clerkenwell, and examining some of the work done in the laboratories, will be afforded to-morrow evening (December 7), when the annual prize distribution and members' and students' conversazione will be held. Sir John A. Cockburn, K.C.M.G., will distribute the prizes.

IN an important article by Dr. William Wallace in the current number of the *Fortnightly Review*, on "the Scottish University crisis," attention is drawn to the urgent need there is for a greatly increased expenditure upon Scottish universities if they are to maintain the reputation they have enjoyed in times gone by. It is urged that a lump sum of not less than 1,500,000*l.* is required to place all the Scottish universities in such a position that their degrees should be regarded as of equal value with those of England, Germany, or even America. Such money is regarded as imperatively necessary for the following main purposes: (1) The conversion of the present skeleton faculties into real teaching organisations; (2) For laboratory and other scientific equipment; (3) For libraries; (4) For the endowment of industrial universities or of genuine industrial faculties in the universities; (5) For the endowment of poor undergraduates; (6) For the endowment of post-graduate research.

DR. OLIVER LODGE made some novel suggestions as to the time, place and purpose of University examinations, in his address to the students of the University of Birmingham on November 28. His proposals amount essentially to this—that examinations should not immediately follow teaching, and that a vacation interval should intervene for private study and revision, quiet thought, assimilation and digestion. Students should not be taken straight from a lecture-room into an examination-room, so that they might tell the examiner what the professor had said before they had time to forget it. So he wished to urge that a long vacation should be left between instruction and examination; that the examinations be held in September instead of at the end of June. If no interval for rumination was afforded during student days, if the unrooted ideas were pulled up for inspection by the examiner at the end of each session, and the student turned loose in the holidays, empty, swept and only partially garnished, for a period of complete idleness before another filling-in process began, then the last state of that man was liable to be little better than the first. The principle underlying Dr. Lodge's proposals is sound enough, but there are difficulties and objections in the application. What, for instance, is to prevent the student who wishes to obtain a good place in the examination at the commencement of the session

from devoting his holidays to study when he ought to be gaining physical strength and enjoying mental relaxation?

THE Emperor of Germany has given his consent to further reforms in the educational systems of the higher schools of Prussia, and a summary of the edict is given in the *Times*. The general education received in the three kinds of schools, the Gymnasium, the Realgymnasium and the Oberrealschule, is to be regarded as of the same value, and as only requiring to be supplemented in so far as for several branches of study and for several professions special preliminary knowledge is necessary which is not included in the curriculum of all three institutions. In accordance with this consideration, the desirability of extending the privileges of the Realgymnasien and the Oberrealschulen is to be kept in view. By this means it is hoped to raise these schools in public estimation, and to render an acquaintance with modern subjects more general. In view of the great importance of a knowledge of English, his Majesty lays stress upon the necessity of giving more attention to that subject in the Gymnasium. English is to be taught as an alternative subject to Greek in all the classes of those schools, except the three highest. Where the local conditions are favourable to the alteration, English is to take the place of French as a compulsory subject in the three highest classes. French, however, is to be retained as a voluntary subject wherever this change is made. The Emperor further regards it as advisable that more time should be given to geography in the higher Realschulen than has hitherto been the case. In the teaching of modern languages importance is to be attached to fluency in speaking and to the understanding of current authors.

SCIENTIFIC SERIALS.

Bulletin of the American Mathematical Society, November.—The only paper in the present number is a note on geometry of four dimensions, by Prof. Lovett, which was read before this society on April 28 of this year. The writer indicates nine well-defined "trends" which the speculations relative to the geometry of n-dimensional space have followed, and directs his work to following up two out of these, viz., the interpretation of this geometry in the light of the theory of groups as exhibited by Lie, Klein and Poincaré and the extension of the methods of ordinary differential geometry to general spaces, *i.e.* as worked out by Christoffel, Beltrami, Cesàro, Darboux and others. This he does by constructing four dimensional space by the method of Lie's theory of continuous groups, and studying curves of triple curvature by the intrinsic analysis developed by Cesàro in his Lezioni di geometria intrinseca.—An account of the proceedings at the recent International Congress held at Paris is furnished by Miss C. A. Scott, in which she abstracts the addresses by Prof. Cantor, sur l'historiographie des mathématiques, and Prof. Volterra, trois analystes italiens, Betti, Brioschi, Casorati. Several of the papers communicated are lightly but clearly handled, and M. Poincaré's presidential address, du rôle de l'institution et de la logique en mathématiques, is concisely analysed. She plainly speaks her mind on many points of detail.—Dr. G. A. Miller gives an account of the 49th Annual Meeting of the American Association for the Advancement of Science so far as it relates to the work of the society. The meeting was held at Columbia University, June 23—30, and from the point of view of scientific work it is said to have been one of the most successful that has been held by the association. About twenty papers were read in section A., some of which are given in brief abstract.—In the "notes" additional particulars (to those given in the October number) are given of the mathematical courses to be followed in the coming winter at British and Continental colleges.—Personal details as to deaths and new appointments, with the usual "new publications," close the number.

IN a paper on new and critical British Algæ, in the *Journal of Botany* for October, Mr. E. A. L. Batters describes no less than three new genera of sea-weeds:—Neevea, belonging to the Bangiaceæ, represented by *N. repens*, endozoic on *Flustra foliacea* at Deal; Rhodophysema (Florideæ), founded on *R. Georgii*, growing on *Zostera marina* off the Scilly Islands; and Erythrodermis (Florideæ), represented by *E. Alleni*, dredged up from 4—6 fathom water at Plymouth.—In the number for November Mr. Pearson describes and figures a new liverwort, *Lejeunea Macvicari*, from Inverness-shire; and Mr. E. S. Salmon a new parasitic fungus belonging to the Erysipheæ, *Uncinula septata*, from Japan.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 15.—"Data for the Problem of Evolution in Man. VI.—A First Study of the Correlation of the Human Skull," by Alice Lee, D.Sc., with some assistance from Karl Pearson, F.R.S., University College, London.

November 22.—"On the Restoration of Co-ordinated Movements after Nerve Crossing, with Interchange of Function of the Cerebral Cortical Centres." By Robert Kennedy, M.A., D.Sc., M.D.

Zoological Society, November 20.—Dr. W. T. Blanford, F.R.S., Vice-President, in the chair.—Mr. Sclater stated that during a recent short stay at Gibraltar he had visited the haunts of the Barbary Ape (*Macacus innuus*), at the top of the Rock, and had ascertained that the herd of these animals was in a flourishing condition, and had considerably increased during the last few years.—An extract was read from a letter from Sir Harry Johnston, K.C.B., containing indications of a supposed new species of the Horse-family (Equidæ) which appeared to inhabit the Great Congo Forest, near the Semliki River, East Africa.—Mr. G. A. Boulenger, F.R.S., exhibited and made remarks on one of the type-specimens of a new species of Protopterus from the Congo, for which he had proposed the name of *Protopterus dolloi*.—Dr. W. T. Blanford, F.R.S., exhibited and made remarks upon a very fine pair of horns and some skins of the Central-Asiatic Wapiti, lent to him for examination by Mr. Rowland Ward.—Mr. F. E. Beddard, F.R.S., read a paper on the Osteology of the Pigmy Whale (*Neobalaena marginata*), based mainly on an examination of one of the specimens of this animal in the British Museum. A detailed description of the skeleton was given, and the features in which it differed from that of other known forms of the Cetaceans were pointed out.—Prof. Howes, on behalf of Prof. Baldwin Spencer, F.R.S., gave a description of *Wynyardia bassiana*, a fossil Marsupial from the Tertiary Beds of Table Cape, Tasmania. It was remarkable as being the first fossil Marsupial obtained from the Tertiaries of Australia, and appeared to be a Polyprotodont, having affinities with the Didelphyid, Dasyurid, and Phalangistid series, which had probably struck off from the rootstock at the period at which the Diprotodonts were in course of evolution.—A communication from Mr. L. A. Borradaile contained an account of a collection of Arthrostracans and Barnacles from the South Pacific.—Mr. Oldfield Thomas read a paper on the Mammals obtained by Dr. Donaldson Smith during his latest expedition from Somaliland by Lake Rudolf to the Upper Nile. Twenty-three species were enumerated, and five forms described as new. Dr. Smith had also obtained some fine examples of the true Bohor of Rüppell (*Cervicapra bohor*) and of the Bushbuck described by Heuglin as *Tragelaphus bor*, which proved to be a tenable sub-species of *T. scriptus*.—Mr. W. L. Distant read a paper on the Rhynchota belonging to the family Pentatomidæ in the Hope Collection at Oxford. It constituted a revision of the catalogue of the Hope Collection written by the late Prof. Westwood in 1837. All the specimens had been examined by the author, and the species relegated to modern genera and much synonymy removed, while several new genera were described in the paper.—A communication was read from Mr. R. C. Punnett, containing an account of the Nemerteans collected by Prof. Haddon in Torres Straits. They comprised examples of seven species, four of which had been previously described, whilst the remaining three were new.

Royal Meteorological Society, November 21.—Dr. C. Theodore Williams, President, in the chair.—A communication was read from the International Meteorological Committee inviting observations of the form, amount and direction of the clouds on the first Thursday of each month during 1901, as well as on the preceding and following days. These observations are to be made in connection with the balloon ascents which will be carried out under the direction of the Aërostation Committee.—Mr. R. H. Curtis exhibited an improved mounting for the lens and bowl of the Campbell-Stokes sunshine recorder, by means of which the glass ball can be quickly and accurately placed centrally in the bowl, where it is secured by clamping screws.—Mr. W. H. Dines read a brief paper on the weekly death-rate and temperature curves, 1890-99. He exhibited diagrams showing the death rate of the thirty-three great towns of England, and also curves of the temperature at Greenwich. The author is of opinion that, from the health point of view, the English climate is one of the best in

the world, and this is proved by the relatively low rate shown in these curves. A pleasanter climate may well be found, but the majority of health resorts to which Englishmen resort in the winter have a higher death rate than London has at the same season, and a far higher rate than any of the country districts of the British Isles.—Mr. H. Mellish also read a paper on the seasonal rainfall of the British Islands. After referring to what had already been written on the subject by others, he proceeded to discuss the data contained in the "Tables of Rainfall, 1866-90," published by the Meteorological Council. He concluded by saying that, as regards the relation between the amount which falls in the wettest and the driest month at any station, it seems to be generally the case that the range is larger for wet stations than for dry ones.

Entomological Society, November 21.—Mr. G. H. Verrall, President, in the chair.—Mr. H. W. Andrews exhibited *Atherix crassipes*, Mg., a Dipteron new to the British list, taken near Ticehurst, Sussex. Mr. Verrall remarked that it was a distinct species, and, like *Leptis*, affected the leaves of alder.—Colonel Yerbury exhibited *Anthrax paniscus* and *Tabanus bromius*, bred from a lepidopterous pupa found in sand at St. Helen's, Isle of Wight, and a new species of Cordylura, taken at Aviemore in July 1899 and June 1900.—Mr. L. B Prout exhibited three male specimens of *Proutia betulina*, Z , and two of *P. eppingella*, Tutt, bred from larvæ taken this season in Epping Forest. He remarked that both species occurred in the same part of the forest, and the larvæ appeared to be attached chiefly to old hawthorns. Excepting in the smaller size of *P. eppingella*, no superficial difference was observable between the two species. The specimens of *P. betulina*, however, emerged about ten days earlier.—Dr. Chapman exhibited some specimens of considerable interest in relation to the question of correspondence or otherwise of the pupal and imaginal wings of *Aporia crataegi*, showing that at this particular stage the imaginal wings presented the markings of the pupal wing, a set of markings which are in a way the reverse of those of the mature imago. He also exhibited specimens of the wings at a later stage, showing the true imaginal markings developed. With regard to these effects, Dr. Chapman explained them to some extent as analogous to photographic effects. It was quite possible, he thought, that light and heat caused a differential effect through the different coloured areas of the pupa.—Papers were communicated on contributions to a knowledge of the Rhyncota, by Mr. W. L. Distant, and an account of a collection of Rhopalocera made at Zomba, British Central Africa, by Mr. P. T. Lathy.

MANCHESTER.

Literary and Philosophical Society, November 27.—Mr. J. J. Ashworth, Treasurer, in the chair.—Dr. Wilson mentioned a peculiarity to which his attention had been called in reference to the bursting of gauge glasses on the engines in the laboratory at the Owens College. It appears that an interval of perceptible length occurs between the first appearance of a longitudinal crack in the glass, from which the steam issues, and the actual burst. The interval was sufficiently long on one occasion to allow the fireman to shut off the steam before the tube collapsed. If the interval be found to occur generally, it is of obvious importance.

DUBLIN.

Royal Dublin Society, November 21.—Prof. G. F. FitzGerald, F.R.S., in the chair.—Prof. J. Emerson Reynolds, F.R.S., presented notes on some recent advances in chemical science illustrated at the Paris Exhibition.—Mr. J. R. Wigham described a method of burning petroleum under pressure for lighthouses and other places where an extremely powerful light is required, and exhibited a working model of the apparatus.—Prof. J. Emerson Reynolds exhibited a series of photographic slides showing various parts of the Paris Exhibition.—Dr. W. E. Adeney exhibited and described the Michelson Echelon spectroscope.—Mr. R. M. Barrington showed a collection of the wings of birds killed by striking Irish lighthouses in their flight.

PARIS.

Academy of Sciences, November 26.—M. Maurice Lévy in the chair.—Action of the earth's magnetic field upon the behaviour of a magnetised chronometer, by M. A. Cornu. As the result of the experiments cited, the conclusion is drawn that it is possible to correct the action of a magnetic field upon a magnetised chronometer, either by a correction formula or by the use of compensators.—On the existence of the nitrides of neodymium and praseodymium, by M. H. Moissan. A claim for priority against M. Matignon.—M. Haller was elected a member of the section of chemistry in the place of M. Ed. Grimaux.—On the definition of certain surface integrals, by M. H. Lebesgue. On fundamental functions and the problem of Dirichlet, by M. W. Stekloff.—On orthogonal systems admitting a continuous transformation group of Combescure, by M. Maurice Fouché.—Solution of a problem of elastic equilibrium, by M. Ivar Fredholm.—On the study of distant storms by means of the telephone, by M. Th. Tommasina. By the use of a coherer and a telephone each change of sign of atmospheric electricity shown on the electro-radiograph of M. Boggio Lera is shown to be accompanied by a sound in the telephone, giving rise to the illusion that the storm is quite close. The apparatus may possibly be of use at sea.—Actinometric measurements at Pamir, by M. B. W. Stankewitch. Observations were made at the passes of Taldik (3590 metres), Kisil Art (4220 metres), and Ak Baital (4650 metres).—On the magnetisation of electrolytic deposits of iron obtained in a magnetic field, by M. Ch. Maurain. Two curves are given, one showing the ordinary magnetisation curve of a deposit obtained as little magnetised as possible, the other the intensities of magnetisation of deposits obtained in constant fields up to 800 C.G.S. units.—Apparatus for localising despatches in wireless telegraphy, by M. Paul Jégou.—Cryoscopic researches, by M. Paul Chroustchoff. The measurements were made with a Callendar and Griffiths electrical thermometer, reading to 0°·0001 C. Experimental results are given for salt, sugar, potassium bromide and sulphate.—New method of estimating arsenic, by M. O. Ducru. In a solution containing ammoniacal salts, and slightly alkaline with ammonia, arsenic acid is completely precipitated by cobalt salts. The precipitate may be treated in one of three ways, dried at 100°, ignited at a low red heat, or the cobalt determined electrolytically, of which the first and third appear to give the best results.—On a general method of separation for the metals of the platinum group, by M. E. Leidié. Metals other than those belonging to the platinum group are eliminated, and the remaining metals transformed into double nitrites. Soda is added to the liquid, and the osmium and ruthenium distilled off in a current of chlorine. The iridium and rhodium are precipitated as double nitrites with ammonium nitrite, and the residual palladium and platinum separated in the usual way.—Direct combination of hydrogen with the metals of the rare earths, by M. Camille Matignon. Neodymium, praseodymium and samarium combine rapidly and completely with hydrogen, the hydrides being dissociable.—On some chlorobromides of thallium, by M. V. Thomas. A description of the method of preparation and properties of the chlorobromide, $TlCl_2Br_4$.—On the selenide of cadmium, by M. Fonzes-Diacon. Crystallised cadmium selenide, CdSe, is rhombohedral, and isomorphous with zinc selenide obtained under similar conditions.—Examination of mineral waters for metals present in minute proportions, by M. F. Garrigou.—On the nitration of di-substituted derivatives of benzene, by M. Ch. Cloez.—Action of nitric acid upon tribromoguaiacol, by M. H. Cousin. Nitric acid gives a quinone, which is the result of a simultaneous condensation and oxidation.—On the presence of seminase in seeds containing horny albumen, by MM. Em. Bourquelot and H. Hérissey. Experiments were made on the seeds of lucerne (*Medicago sativa*) and indigo (*Indigofera tinctoria*). These contain, before germination, a small proportion of a soluble ferment, seminase, capable of liquefying their horny albumen and transforming it into assimilable sugars, these sugars forming the first nutriment of the embryo at the commencement of its development.—Osmotic communication in the normal marine invertebrate, between the internal and external media of the animal, by M. R. Quinton.—The adipose body of the Muscides during histolysis, by M. F. Henneguy.—Experiments on teleogony, by Mlle. Barthelet.—On polymorphism of stems in a single species, by M. Marcel Dubard. The Miocene basalts in the neighbourhood of Clermont, by M. J. Giraud.—The effects of working certain groups of muscles, upon others which do no work, by Mlle. I. Ioteyko. A discussion of the previous note of MM. Kronecker and Cutter upon the same subject.—Seasonal variations of temperature at different heights in the atmospheres, by M. Léon Teisserenc de Bort.

NEW SOUTH WALES.

Royal Society, September 5.—The President, Prof. Liversidge, F.R.S., in the chair.—The language, weapons and manufactures of the aborigines of Port Stephens, New South Wales, with two plates, by W. J. Enright.—The past droughts and recent flood at Lake George, by H. C. Russell, C.M.G., F.R.S. It was shown that at the end of 1874 Lake George was at its maximum depth during the past seventy years, the depth then being 24 ft.; from that date the water gradually decreased, rising sometimes during heavy rains, and on February 25, 1877, the water was only 10 ft. 9 in. deep. At this time the author put up an automatic gauge, which recorded every change until it became too low for the machine to work, and exact measures were then carried on by hand. Meantime the level varied with the seasons, until in 1890, a very wet year, the lake was 12 ft. 11 in. deep; and after this the lake level fell faster than ever recorded before, and on March 28, 1900, the depth was only 0 ft. 10 in., a fall of 12 ft. 1 in. in six years. During 1895 the evaporation was most rapid, the hot and windy weather carried the water away, not only by evaporation but also as spray into the forest, and the total loss of water in that year was 5 ft. 4 in.—Note on an obsidian "bomb," by R. T. Baker. The specimen described in this note is not quite perfect—a portion having been broken off when it was discovered. It has a form quite unusual to those previously recorded from Eastern Australia, but resembles those from Western Australia and the interior of the continent. It is not unlike one found in Tasmania in 1897. It is sub-globose in shape, the surface being much indented with air pores and globulites; it has a very dark green or almost black, glassy appearance, and measures 1 in. in diameter, and ⅝ in. in thickness, and has a specific gravity of 2·456 at 15° C. It was found at O'Connell, near Bathurst, by Messrs. A. Walkes and Lester, some feet below the surface, whilst sinking for gold.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part 2 for 1900, contains the following memoirs communicated to the Society:—

April 9.—W. Voigt: On the present state of our knowledge of the elasticity of crystals (report for the Paris International Congress of Physics).

February 3.—E. Landau: The function $\varphi(n)$ in the theory of numbers, and its relation to Goldbach's theorem.

May 19.—H. Winkler: On the segmentation of unfertilised ova under the influence of sperm-extractives.—G. Mittag-Leffler: On the generalisation of Taylor's theorem.

June 30.—E. Ehlers: Magellanic annelids, collected by the Swedish Expedition to the Straits of Magellan.—J. Orth: Researches at the Göttingen Pathological Institute (Report vii.).

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 6.

ROYAL SOCIETY, at 4.30.—The Histology of the Cell Wall, with Special Reference to the Mode of Connection of Cells. Part I. The Distribution and Character of "Connecting Threads" in the Tissues of *Pinus sylvestris* and other Allied Species: W. Gardiner, F.R.S., and A. W. Hill.—On the "Blaze Currents" of the Frog's Eye-ball: Dr. Waller, F.R.S.—On a Bacterial Disease of the Turnip (*Brassica napus*): Prof. M. G. Potter.—The Micro-organism of Distemper in the Dog, and the Production of a Distemper Vaccine: Dr. S. M. Copeman.—On the Tempering of Iron Hardened by Overstrain: J. Muir.

CHEMICAL SOCIETY, at 8.—Ballot for the Election of Fellows.—Santalenic Acid: A. C. Chapman.—Ammonium Bromide and the Atomic Weight of Nitrogen: A. Scott, F.R.S.—Interaction between Urethanes and Primary Benzenoid Amines: Dr. A. E. Dixon.—The Decomposition of Chlorates. Part III. Calcium Chlorate and Silver Chlorate: W. H. Sodeau.—Nitride of Iron: Gilbert J. Fowler.—The Heat of Formation and Constitution of Iron Nitride: Gilbert J. Fowler and Philip J. Hartog.—Relationships of Oxalacetic Acid: H. J. H. Fenton, F.R.S., and H. O. Jones.

RÖNTGEN SOCIETY, at 8.—Exhibition and Description of a Stereoscopic Fluoroscope and a New Rotary Mercury Break: J. Mackenzie Davidson.

LINNEAN SOCIETY, at 8.—On some New Foraminifera from Funafuti: C. Chapman.—On British Thrifts: G. Claridge Druce.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Continuation of Discussion on Mr. Langdon's paper.

FRIDAY, DECEMBER 7.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Dock Gates: F. K. Peach.

GEOLOGISTS' ASSOCIATION, at 8.—The Zones of the White Chalk of the English Coast. II. Dorsetshire: Dr. A. W. Rowe.

MONDAY, DECEMBER 10.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Expedition to the Barotse Country and through Africa to the Nile: Major St. Hill Gibbons.

SOCIETY OF ARTS, at 8.—Electric Oscillations and Electric Waves: Prof. J. A. Fleming, F.R.S.

TUESDAY, DECEMBER 11.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Signalling on the Waterloo and City Railway; and Note on the Signalling of Outlying Siding Connections: A. W. Szlumper.—Signalling on the Liverpool Overhead Railway: S. B. Cottrell.

WEDNESDAY, DECEMBER 12.

SOCIETY OF ARTS, at 8.—The Treatment of London Sewage: Prof. Frank Clowes.

THURSDAY, DECEMBER 13.

ROYAL SOCIETY, at 4.30.—*Probable* papers: On the Spectrum of the More Volatile Gases of Atmospheric Air, which are not Condensed at the Temperature of Liquid Hydrogen. Preliminary Notice: Prof. Liveing, F.R.S., and Prof. Dewar, F.R.S.—Additional Notes on Boulders and other Rock Specimens from the Newlands Diamond Mines, Griqualand West: Prof. Bonney, F.R.S.—The Distribution of Vertebrate Animals in India, Ceylon and Burma: Dr. W. T. Blanford, F.R.S.—Elastic Solids at Rest or in Motion in a Liquid: Dr. C. Chree, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—The Syzygetic Theory of Orthogonal Bivariants: Prof. Elliott, F.R.S.—On Discriminants and Envelopes of Surfaces: R. W. Hudson.—Note on the Inflexions of Curves with Double Points: H. W. Richmond.—On some Properties of Groups of Odd Order, ii.: Prof. Burnside, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Possible continuation of Discussion on Mr. Langdon's paper.——*Time permitting*: Rapid Variations in the Current through the Direct Current Arc: W. Duddell.

CHEMICAL SOCIETY, at 8.30.—Rammelsberg Memorial Lecture: Prof. H. A. Miers, F.R.S.

FRIDAY, DECEMBER 14.

PHYSICAL SOCIETY (Royal College of Science), at 5.—(1) Electric Inertia; (2) The Effect of Inertia on Electric Currents in a Rotating sphere: Prof. A. Schuster, F.R.S.—Exhibition and Description of a Quartz-Thread Gravity-Balance: Prof. R. Threlfall, F.R.S.—On the Theory of Magnetic Disturbances by Earth Currents: Prof. A. W. Rücker, F.R.S. Notes on the Practical Application of the Theory of Magnetic Disturbances by Earth Currents: Dr. R. T. Glazebrook, F.R.S.—The New Physical Laboratories of the Royal College of Science: Prof. A. W. Rücker, F.R.S.—Exhibition of a Set of Half-Seconds Pendulums: W. Watson.

ROYAL ASTRONOMICAL SOCIETY, at 8.

MALACOLOGICAL SOCIETY, at 8.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Power-Gas and Large Gas-Engines for Central Stations: H. A. Humphrey.

SATURDAY, DECEMBER 15.

ESSEX FIELD CLUB (Essex Museum of Natural History, Stratford), at 6.30.—Notes on the Mollusc *Paludestrina jenkensi*, Smith, in Essex and elsewhere: A. S. Kennard and B. B. Woodward.—Aquatic Autocrats and Fairies (Lecture): Fred. Enock.

CONTENTS.

THURSDAY, DECEMBER 13, 1900.

ORGANOGRAPHY AND ITS RELATIONS TO BIOLOGICAL PROBLEMS.

Organographie der Pflanzen, insbesondere der Archegoniaten und Samenpflanzen. Von Dr. K. Goebel. Zweiter Theil. 2 Heft: Pteridophyta und Samenpflanzen. Mit 173 abbild. im text. Pp. xvi + 385 to 648. (Jena: Gustav Fischer, 1900.)

THE volume before us forms a further instalment of the large treatise on the organography of plants upon which Prof. Goebel is engaged. The part just published deals with the vegetative organs of the flowering plants, and, in a lesser degree, with the sporophyte and gametophyte of the vascular cryptogams.

It is needless to remark that the book teems with information, and, as might be anticipated, the author has drawn largely, for purposes of illustration, on the rich stores of material collected by him during his travels in various parts of the world. It is possible, however, that a layman on reading the book would arrive at the conclusion that in this particular field (of organography) other botanists had displayed far less activity than might have been expected from them, and would thus give them less credit than a closer acquaintance with either literature or the class-room would show they deserved.

The plan of the book is partly morphological, but woven into the morphological warp there is also the biological woof, and the author has emphasised, in a way which few could have done so well and, perhaps, no one more fully, the interdependence of these two groups of factors which so largely determine the actual form of existing plants. Goebel has long been known as an exponent of the concrete, and throughout the treatise one constantly finds traces of his antagonism towards that idealism into which, if the function of an organ be neglected, the morphologist is even still apt to stray.

Whilst tracing the various modifications which a given structure—*e.g.* a root—may exhibit in different plants, or in different parts of the same individual, the author constantly insists that these are, in fact, due to a deviation from the ordinary course of growth which commonly culminates in the formation of a normal root. Similarly, though it is more difficult to prove the point owing to their greater variety (depending on their more varied environment), the author argues that the modified leaf structures, scales, thorns, and so on, are brought about by causes acting on the developing primordium of what would, if unchecked, become a foliage-leaf. This latter is for Goebel the actual typical leaf, and from it, by an exaggeration or attenuation of parts which are already recognisable during its earlier stages, the modification occurring in any given example proceeds. He strenuously opposes the view advocated by some writers that the leaf-primordium is an indifferent structure, and regards it as normally destined to give rise to an ordinary leaf. He has himself, more, perhaps, than any one else, shown how easy it is in some cases to interfere with those causes or sequences of events leading to the modification of such an organ, and thereby to effect a reversion in favour of the more primitive organ to take place. Probably most people would be inclined to admit that, on the whole, the main lines of evidence go to prove that the obvious assumption made by Goebel in this connection with regard to the original character of the organ is a valid one.

It must, however, be confessed, and any one at all conversant with contemporary literature will recognise the fact, that there exists some danger of attaching a one-sided importance to the readiness with which organisms adapt themselves to the exigencies of a changed environment. For the response in form and structure is often so direct and obviously purposeful that more stress is apt to be laid on the stimulus itself than on the nature of the body to be stimulated, with its complex and varied mechanism, and there are some who have gone so far as to read into this purposeful variation an immediate explanation of the formation of new or incipient varieties; as though the real fact which mainly stands in need of analysis were not the very one constituted by this self-same *purposeful* character of the response. And indeed it would appear, upon reflection, that this form of response is itself the result of the operation of natural selection which has acted by eliminating the chance of leaving descendants from all those competitors in whom the reaction to a given set of conditions happened to fall short of a certain standard of perfection. It need not necessarily follow that all must have varied in an identical manner, but those that failed to comply, by *some* suitable change or another, with the requirements imposed by the new conditions, must inevitably be ousted by their more gifted rivals, and if these assumed changing conditions periodically recur, then the process of elimination will result in those only being left in which the power to respond accurately (*i.e.* purposefully), and it may be rapidly, to a particular change has been best developed and cultivated.

It is obvious that a similar result, *mutatis mutandis*, would follow if a complex variety of stimuli be substituted for the simple case touched on above, and thus a protoplasmic mechanism is gradually selected and perfected which, when stimulated by any means to which there can be a response at all, will reply by the corresponding reaction normal for that species or race. But though normal in kind for the race, its degree will vary in different individuals, as any one can readily prove by direct observation. Hence it at once becomes subject to the operation of natural selection. Naturally, so long as a particular stimulus is absent the corresponding response, however well tuned and ready, will remain in abeyance as a latent potentiality.

A study of plants reveals numerous examples of this. Amphibious plants frequently are able to assume alternative characters, respectively fitted for either a terrestrial or an aquatic habit, and it depends entirely on the nature of the stimulus arising from the environment as to which of the two types of structure shall appear. Such plants, during their species-life, have been repeatedly exposed to vicissitudes of a somewhat extreme character, and the latent ability to change so as to adapt themselves more fully to altered circumstances must have played no unimportant part in securing the survival of their race. Many other examples could be quoted to show how important for stationary beings like plants is the possession

of a very plastic organisation, that is, one which will respond readily and *accurately* to the demands of the external conditions of life. For plasticity is clearly only of use (and therefore will come to a like extent within the purview of natural selection) in so far as it will provide the organism with the power of striking the right note in response to a particular call.

On the other hand, there are plants which may have become, for example, specially selected on account of their ability to flourish in dry, hot, desert lands. Such plants might be expected to retain slender powers of responding in a manner favourable to the continuance of life under opposite hygrometric conditions; and every one is aware how extremely intolerant of moisture are the cacti and some other xerophytic plants. Nor is this surprising, seeing how trivial a part the development of a purposeful adaptation to satisfy the needs of a damp environment can have played in their ancestral experience, and indeed the chance of any individual amongst them possessing the power of responding quickly and appropriately to such conditions, to which they are never exposed, is an exceedingly remote one. It is otherwise with species that inhabit regions which, though usually dry, are occasionally or periodically exposed to different conditions. That the plants living in such places, though they may be mainly of a xerophytic habit, nevertheless retain the faculty of withstanding wet is precisely what one would have been led to anticipate, and there are plenty of examples in which the alternation of dry and wet seasons is accompanied by a change in habit analogous to that exhibited by our own trees in summer and winter respectively. An immense weight of evidence has been accumulated by those who have helped to elucidate these matters which goes to prove that the power to vary in any given direction is possessed in an unequal degree, not merely by individuals of the same species, but even in those growing side by side, and thus apparently exposed to very similar conditions.

This fact at once emphasises the importance of the preexisting *internal* factor of variation, and it also explains the existence of a criterion which can determine what individuals shall survive in the struggle imposed by new or changing conditions. The particular variation elicited in any given instance is merely the outward and visible sign of the operation of an inward organisation or mechanism. It is the latter which, forming an integral part of the parental constitution, will be transmitted to the offspring. And if those individuals which possess the special organisation in the highest degree are thereby enabled to leave the most vigorous or favourably situated descendants, that character, which is its outward token, will become correspondingly strengthened till it comes to form a mark of the race. It is the function of the environment to prove the individual capacity in that contest where the race is emphatically to the swift and the battle to the strong.

Hence, it would seem that not variability only, but that special (purposeful) form of it which enables so many organisms to make suitable responses to divergent conditions of life ought to be, as the outcome of the effect of natural selection, a feature of very general occurrence; and it ought to be most strongly developed in organisms living under changing or changeable conditions, and such is found to be the case. One may almost assert that the purposefulness of a particular reaction is a measure of the perfectedness of the stimulable mechanism, itself a heritage transmitted through a long ancestral line of individual bodies.

This view of the matter is obviously in no wise altered, if we admit the occurrence of sudden or discontinuous variations. For these also are themselves congenital in their origin, and all that the environment can do is to encourage the manifestation of a variation (if a favourable one) in as high a degree as the organism can develop it. Nor is the position affected if we allow that a structural reaction may proximately result from a change in the metabolic processes of the organism, such as Sachs, and Goebel following him, have supposed. In fact, there are some familiar instances which hardly admit of any other explanation, as, for example, when different kinds of galls are produced on the same individual oak-tree by different insects. Facts such as these merely shift inquiry to another stage, and it is certainly not less difficult, in these and similar cases, to account for the particular antecedent reactions going on within the plant in such a way as to produce a substance capable of acting as an appropriate stimulus, which shall provoke a reaction in the plant useful to the grub which originates it.

Into the questions as to the origin of the causes of variations themselves, this is naturally not the place to enter; nor does a consideration of the problems concerned with the nature of those variations which may arise correlatively, or which are more or less obscurely conditioned by remote causes residing within the organism itself, and which may appear suddenly, without any immediate reference to their adaptedness to contemporary needs, fall within the scope of this article. It is enough to emphasise the point that the occurrence of purposeful reactions to specific stimuli is really in complete harmony with the operation of natural selection acting through the medium of a congenitally varying organisation.

Turning again to the subject-matter of Prof. Goebel's book, one finds that not only is it replete with interesting results of biological inquiries, but that there are scattered through its pages excellent little essays on morphological subjects. As an example of the former may be cited the explanation of the mechanism which brings about the dehiscence of the antheridia, a topic which has already formed the basis for investigations published from the author's laboratory. The instance of Azolla, too, in which the lower leaf lobe is shown to have an absorbent function, is attractive when the analogous case of Salvinia is recalled.

The critical treatment of the structure of the grass embryo is an admirable piece of comparative morphology. Prof. Goebel regards the cotyledon as consisting of the scutellum, epiblast and the sheath or coleoptile. His views are supported by evidence drawn from a consideration of a large number of other monocotyledons, especially the Cyperaceæ, and whether one agrees with his conclusions or not, one cannot but praise the way in which the evidence for them is collected and marshalled. The views put forward as to the homologies existing between the cells formed within the germinating microspores of some of the vascular cryptogams will probably provoke criticism, as will also the suggested phylogeny

of the gymnosperms, which the author appears to regard as derived partly from the Ferns and partly from the Lycopods.

As regards the book, viewed as a whole, it is impossible not to feel that, in spite of—perhaps partly in consequence of—its extraordinary wealth of illustration, it does not help us much farther towards a more general conception of the value and wider relations of organography as a whole. But, nevertheless, the experimental line of inquiry in this field, which Goebel himself has so ably pursued, is one which will certainly prove a fruitful one, judging from the results which have even yet accrued. And for the clear indication of this, as well as for the bringing together such a vast store of facts, the author has thoroughly earned the gratitude of his fellow-workers. It is just because there is so much of good in the book that it is difficult to avoid giving expression to that kind of gratitude which still hopes for something yet more satisfying. J. B. FARMER.

THE HISTORY OF THE DEVIL.

The History of the Devil and the Idea of Evil. By Dr. Paul Carus. 8vo. pp. xvi+488. (London: Kegan Paul and Co., Ltd. Chicago: The Open Court Publishing Company, 1900.)

THE volume before us is one of considerable interest, but we must say at once that we think the history of the Devil and of the idea of evil should have been treated in a manner different from that which has been adopted by Dr. Paul Carus. The discussion of the idea of evil is a matter for the philosophical thinker, it seems to us, and the subject cannot be threshed out in detail in a single volume by any writer, however able he may be; the history of the manner in which the Devil, *i.e.*, the personification of evil, has been depicted by various peoples at various times in various places over the earth, is quite a different subject, and is, likewise, one which cannot be treated adequately in a single small volume. Dr. Carus, however, has tried to deal with *both* sides of this complex subject in one volume, and, it must be confessed, he will, in consequence, not satisfy either the philosopher or the iconographer. His book is well printed and well illustrated—though we certainly do not admire the shadowy "ghost" pictures printed in a sickly green colour on several of the pages—and to many readers it will be of interest, and probably of use also, for it may stimulate them to investigate the subject for themselves. In eighteen chapters, which vary considerably in length, the history of the Devil and the idea of evil are discussed in connection with the evidence derived from pictures, reliefs, &c., from Egypt, Akkad, Babylonia, Persia, Judea, India, China, Europe, and other countries, but Dr. Carus has not collected all the facts which he ought to have gathered together, and his deductions from those he gives are hardly correct. We do not think that "the belief in good spirits tended towards the formation of the doctrine of Monotheism," or that "the belief in evil spirits led naturally to the acceptance of a single supreme evil deity." Prehistoric man peopled all earth, air, sea and sky with spirits, some of whom were supposed to be hostile to him, and others benevolent; and he regarded a spirit as good or evil according to whether it did him good or evil. When a series of good harvests came to him, or he was singularly fortunate in love, or the chase, or war, he made up his mind that the good spirits had succeeded in destroying the power of those who were evil. In process of time, to certain evil and to certain good spirits extraordinary powers were ascribed, and eventually the idea of the existence of a prince of evil, as well as of a prince of good, was formulated; terror and ignorance were the chief constituents in the worship of primitive man, and physical and moral attributes, as well as cause and effect, were often confounded by him.

Dr. Carus regards the old Egyptian god Set as the equivalent of the Devil of the later peoples of the West, but this is only partly true. He was a nature power and was the twin brother of Osiris according to one legend, and the twin brother of Horus the Elder according to another. He was the male counterpart of Nephthys who, as is well known, was not hostile to Osiris, and he must not be confounded with Âpep, the mighty enemy of Rā, the Sun-god; Set and Horus together held up the ladder whereby the deceased entered heaven, and both gods gave him a helping hand in mounting it. Dr. Carus is mistaken when he says that Set "was converted into Satan with the rise of the worship of Osiris." We know nothing about the rise of the worship of Osiris, but we learn from the Pyramid Texts that in the fifth dynasty, when the worship of Osiris was universal in Egypt, Set was regarded as a benevolent god and a friend of the deceased. In speaking of Akkad and the early Semites, Dr. Carus is either credulous or rash, for, after saying that the Babylonians "possessed several legends which have been received into the Old Testament," he mentions a legend of the Tower of Babel and of the "destruction of corrupt cities by a rain of fire," reminding us of Sodom and Gomorrah. The text on which he relies for the legend of the Tower of Babel is, of course, K. 3657 in the British Museum, but a recent examination of the tablet proves that it has nothing to do with the Tower of Babel; as for the legend of the cities which were destroyed by "a rain of fire," we cannot imagine what the authority can be. We may mention, in passing, that many of Dr. Carus's authorities are altogether obsolete, and it is possible that one of them has led him astray on this point. His interpretations of Babylonian scenes, too, are not always correct. Thus on p. 40 the "Chaldean Trinity" is not blessing the tree of life, but is merely appearing above the conventionalised representation of the palm tree to the priest who is worshipping before the image of the god; similarly, the statement (p. 46) that the bronze tablet of the de Clercq Collection is a representation of "the world in the clutches of an evil demon" is erroneous. Any account of the demonology of the Assyrians and Babylonians which does not take into account the *Shunpu* and *Maklu* series of magical tablets which have been recently published by Tallquist and Zimmern must of necessity be most incomplete, and we are not a little surprised that Dr. Carus should have undertaken the task without doing so. The demonology of the Israelites is dismissed in nine pages, and this section of the book is most disappointing; in recent years many workers have investigated the Hebrew side of the subject of devil-lore, and an extremely interesting chapter might have been compiled from their writings. The famous

old work of Eisenmenger alone would have afforded him abundant material for a very long essay wherein every statement might have been founded upon fact.

In the chapters of Dr. Carus's work which are devoted to the "Dawn of a New Era" and "Early Christianity," the same complaint must be made, *i.e.*, he has not used existing materials. Who in these days would attempt to write about Gnosticism without giving a good account of the Pistis Sophia, or of the Book of Ieu, works from which the most valuable information on the subject is to be derived? It seems almost as if Dr. Carus had written his book to suit the pictures which he gives, without paying any attention to the system or arrangement of his work. In a treatise of such pretensions we should expect the account of the demonologies of the various Semitic nations to be kept together, and, as the devils of the Gnostics and early Christians were descendants of the denizens of the Egyptian underworld, they ought to have been described in a connected and systematic manner. It is doubtful how far the histories of the Inquisition and of the persecution of witches have any right to be in a book of this kind, but if they have, they should have been greatly shortened; in fact, Dr. Carus's work needs careful editing by a skilful but somewhat severe editor. As a picture book it is interesting enough, but as a scientific contribution to the history of an interesting and important subject it is, in our opinion, of little value.

SIR H. MAXWELL'S "MEMORIES OF THE MONTHS."

Memories of the Months. Second Series. By the Right Hon. Sir Herbert Maxwell, Bart. Pp. xv + 295. Illustrated. (London: E. Arnold, 1900.)

IT falls to the lot of but few among us to be all-round sportsmen, good naturalists, entertaining and versatile writers, and philosophers to boot; and yet all these varied and valuable accomplishments are the attributes of the author of the delightful and entertaining volume before us. A few years ago, as the author tells us in the preface, he published selections from his note-books of several seasons under the title quoted above, and these met with such a favourable reception that, at the request of numerous readers from both sides of the Atlantic, he has been induced to print a second series. And the public are decidedly the gainers by this resolve. For whether discussing the kind of salmon-fly best suited to any particular season or river, the utility or otherwise of birds or mammals commonly persecuted by the farmer and the gamekeeper, the kinds of shrubs and plants best suited to escape the depredations of rabbits, the ruthless slaughter of egrets for the sake of their so-called "osprey" plumes, or the accident by which the skeletons of the iguanodons of Bernissart were preserved for the delectation and wonderment of the present generation, he is equally at home, and equally free from any suspicion of dulness and pedantry.

Nothing, indeed, seems to come amiss to Sir Herbert i the matter of a text, and he has the rare faculty of making an extract from some abstruse scientific paper as full of interest as are his observations on the mammals, birds and fishes with which he has come in contact in the ordinary course of a country life or in his field sports.

Among the subjects to which the author has paid special attention is the so-called vole-plague, which wrought devastation some years ago over wide districts in Scotland. Of the committee appointed to investigate the causes of this invasion, and, if possible, to suggest remedies, he was appointed chairman. And he gives a graphic account of the scene which met the eye during the visits of the committee to the afflicted area, mentioning the extraordinary number of short-eared owls which flocked to the feast, and of their equally remarkable fecundity as its result. Lappwings, too, are birds which come in for a special share of his attention; and although he apparently considers that much harm has not been done thus far, yet he urges that shooting a bird at one season and taking its eggs at another, or even conducting both operations simultaneously, is a sure road to its eventual extermination. While deprecating any interference with the collecting of these plovers' eggs, he suggests that the slaughter of the birds themselves should be prohibited.

An enthusiastic angler, the author holds out hopes of the possible rehabilitation of the salmon in the upper reaches of the Thames, stating that even at the present day the condition of the water at the mouth of that river is such as to offer no barrier to the upward passage of the fish. But he points out that as there are now no salmon-rivers discharging in the neighbourhood of the Thames estuary, it is essential that young salmon must be turned down in that river itself, when there would be hope that some of them would return after their first excursion to the sea. From Thames salmon the transition is easy to the question as to whether *Salmo salar* really abstains from food while in fresh water. In regard to this latter point, Sir H. Maxwell states that the experience of many anglers is practically in accord with the results of the investigation carried on by the Scottish Fishery Board, as detailed in a "blue-book" published in 1898, namely, that salmon do, as a rule, fast during the period in question. Against this evidence is, however, advanced the undoubted fact "that salmon in fresh water do take and swallow worms, minnows, and similar objects." And the pertinent question is asked with what object they take them if not to eat. "The simplest solution is probably the true one—namely, that even a physiological fast is compatible with occasional and irregular impulses of appetite, which exactly corresponds with the well-known capriciousness of salmon in taking any lure."

But to follow the author further in his interesting discussions on fish and fishing would spin out this notice to an inordinate length. And it ought to be mentioned that the mole is one of the animals he considers should be protected rather than destroyed, as it appears to be of incalculable value in destroying the larvæ of "daddy-long-legs" and other equally noxious grubs. On the other hand, Sir Herbert has not a single good word to say for the rabbit, which he terms an "accursed" creature.

Hitherto we have referred to the author's zoological and sporting notes; but an equal degree of interest is taken by him in botany, and the mention of the extraordinary abundance of holly blossom in the home counties during the summer of 1899, coupled with his observations on

the remarkable "mimicry" of the plane by the sycamore, will serve to indicate the amount of attention bestowed by the author on botanical subjects. The incident related on page 87, narrating how a Scotch minister caused all the daffodils in his churchyard to be mown down because his wife regarded yellow as a vulgar colour, is a curious example of mid-century "æstheticism." To those fond of their gardens, the hints given as to the kinds of shrubs and herbaceous plants that flourish best in this country will be acceptable.

With the number of subjects on which the author touches it would not be surprising if he fell here and there into error. And yet there are but two passages which we have found occasion to criticise in this respect. In the first of these (page 89) we fail to realise how ice is likely to have had any share in the transport of the remains of the Bernissart iguanodons. The other is the statement (p. 46) that the nightjar, or goatsucker, is a relative of the swallow, whereas it is, of course, to the swifts that this bird is really allied. That the statement is not due to an accidental slip of the pen is proved by its repetition on page 233. These, however, are but trivial blemishes. And to whatever page he may turn, the reader can scarcely fail to be interested in what the author has to tell him. Whether, indeed, to while away an idle half hour at home, on a railway journey, or as a companion in the field, it would be difficult to find a more entertaining and instructive work of its kind. The epithet "delightful" suits it exactly. R. L.

OUR BOOK SHELF.

Cinématique et Mécanismes, Potentiel et Mécanique des Fluides. Cours Professé à la Sorbonne. Par H. Poincaré; redigé par A. Guillet. Pp. i + 385. (Paris: Carré et Naud, 1899.)

THIS book is edited from a course of lectures given at the Sorbonne. The first part deals with the kinematics of rigid bodies in two and in three dimensions, including the theories of roulettes, of acceleration centres and of relative motion; and concludes with a chapter on simple mechanisms. These are all well-worn topics, and afford little opportunity for novelty of treatment. In the few pages devoted to finite rotations we notice, however, an elegant method of investigating Rodrigues's formulæ which is, at all events, not current in this country. The exposition is marked throughout by the author's usual facility, and the illustrations are well chosen. A severe taste might perhaps take exception to the way in which analysis and geometry are continually mixed up in the proofs, but a course of lectures intended primarily for a special class of students is not to be judged by the same canons as a formal treatise.

The second part gives, in about 180 pages of large type, a rapid sketch of the theory of the potential, the attraction of ellipsoids, hydrostatics and hydrodynamics. A number of leading propositions are introduced, but the treatment is necessarily fragmentary, and in some instances it might be difficult to account for the precise selection which has been made. The brief chapter on hydrodynamics is disappointing. We notice, in particular, that Poisson's proof of Lagrange's velocity-potential theorem is reproduced without a word of warning as to its defects; and on p. 330 we have the following mysterious sentence: "On a discuté la question de savoir si un liquide visqueux est encore soumis au théorème de Lagrange; *les opinions sont partagés!*" Again, on p. 339, the remark: "Il est impossible de déterminer théoriquement le coefficient de contraction," might surely be qualified. It is a little strange to find the labours of Stokes and Kirchhoff on these points entirely ignored, even in an informal publication like the present. The absence throughout of all reference to authorities is, indeed, to be regretted; such references can, of course, be only sparingly made in actual lectures, but they might well be introduced in the process of editing.

It would be ungracious not to add that although, from the nature of the subject, the present treatise is not likely to excite such widespread interest as some of its predecessors, probably few readers will be found to lay it down without a fresh feeling of admiration for the energy and versatility of its author. H. L.

A Contents-Subject Index to General and Periodical Literature. By A. Cotgreave. Pp. xii + 744. (London: Elliot Stock, 1900.)

THIS is an attempt to bring together and classify in alphabetical order the noteworthy contents of periodicals and some other publications.

Several indexes to periodical literature are in existence, and are appreciated by people who have cultivated the habit of verifying references. Mr. Cotgreave has produced an index which will prove a handy and inexpensive guide, and an examination of it suggests that a similar work, prepared by a body of experts instead of one man, and issued periodically, would be of distinct value.

The index is not complete—nor does it pretend to be, but it is a praiseworthy attempt to classify a mass of heterogeneous articles, books and papers into subjects. Any one desirous to know a few contributions on any subject has only to refer to the index and he will find some to serve his purpose, though not always the best. We are only concerned with the scientific subjects, and have examined the entries from this point of view. The result is not very satisfactory, for some of the best contributions to science do not appear—at any rate where we should naturally expect to find them. Why should Barff's "Chemistry" and Reynolds' "Chemistry" be selected as containing accounts of the composition of air, while many other much better descriptions have been published? Why, again, should Johnston's "Chemistry of Common Life" be the only book given under the composition of air? Under physical geography there are six titles, three of which are unimportant; the only title under natural philosophy is Mitchell's "Orbs of Heaven"; an article on cellulose is classified under natural science; Balfour Stewart's Physics Primer is the only book cited under the title "laws of electricity"; Ashby's "Physiology" is the only reference given for a description of the metric system; the British Museum catalogue and introduction to the study of meteorites is not mentioned under meteorites; and many other similar cases could be given. We understand, of course, that the index is an eclectic one, and are willing to acknowledge that much work must have been expended in its preparation; but its limitations and imperfections must nevertheless be pointed out. If it is borne in mind that the book only contains a general survey of literature, it will be found of service.

Workshop Mathematics. By Frank Castle, M.I.M.E. Part i., pp. viii + 154. Part ii., pp. ix + 177. (London: Macmillan and Co., Ltd., 1900.)

PROF. PERRY'S persistent advocacy of a system of mathematical instruction adapted to modern requirements is bearing fruit in the shape of text-books, which will probably do more to induce teachers to adopt rational methods than the most convincing statement in favour of them. Mr. Castle has already prepared a book on "Practical Mathematics" which covers substantially all the subjects in the syllabus drawn up by Prof. Perry for

the Board of Education, South Kensington. The two little books under notice have been written in the same spirit, and contain some sections from the previous volume, but the treatment is more elementary and many new exercises are given.

In Part i. the subjects dealt with belong to arithmetic, algebra and the mensuration of parallelograms, triangles and polygons. Prominence is given to contracted methods, use of decimals, and explanations of algebraical expressions. Scales, calipers, and other simple measuring instruments are described in the chapters dealing with mensuration, and their use is well exemplified. Part ii. is devoted to logarithms, the slide rule, mensuration of circles, ellipses and irregular plane figures, volumes and surfaces of solids, more difficult algebraic expressions than are given in Part i., and the graphic representation of varying quantities. Among noteworthy points in this part may be mentioned the clear account of uses to which a slide rule may be put, the descriptions of planimeters, and the ingenious uses made of squared paper in the section on graphic representation.

The books are full of exercises illustrating the applications to every-day problems of the principles described, and at the end of Part ii. a set of tables of logarithms and anti-logarithms is given, to enable the student to work out problems by logarithms when convenient. It would be too much to say that the books contain an ideal course of mathematics for technical students, but they may fairly claim to provide far more inspiring information and serviceable exercises than can usually be found in text-books designed for use in schools.

Exercises in Natural Philosophy, with Indications how to Answer them. By Prof. Magnus Maclean, D.Sc., F.R.S.E. Pp. x + 266. (London: Longmans, Green and Co., 1900.)

The ability to deal with quantitative results is an essential qualification of a student of physical science. Laboratory work provides some material for the exercise of this faculty, but it is often necessary to use data obtained by others, and to work out problems other than those which are afforded by the student's own practical work. Dr. Maclean's book contains numerous exercises of this character, covering most of the subjects studied in courses of physical science, and many worked-out examples of typical cases suggesting methods of solution for those which follow. Wisely used, the book will provide teachers with useful exercises in mathematics applied to physics, and will make a convenient supplement to text-books in which such exercises are not given. Many text-books do contain questions upon the subjects dealt with, but even in these cases some good additional problems for solution could be selected from the book under notice.

Tables of useful data and physical constants are printed at the end of the volume.

Memoirs of the Countess Potocka. Edited by Casimir Stryienski. Authorised translation by Lionel Strachey. Pp. xxiv+253. (New York: Doubleday and McClure Company, 1900.)

These memoirs cover the period from the third partition of Poland to the incorporation of what was left of that country with the Russian Empire. They deal with episodes—more or less romantic and interesting—in Countess Potocka's career, referring to journeys, Court balls, and Napoleon I., between 1812 and 1820. The authoress died, at the age of ninety-one, in Paris, where her brilliant salon held no insignificant place in the gilded pleasures of the Second Empire. There is little of interest to scientific readers in the memoirs; but one or two incidents referring to astrologers are amusing.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Inverse or "a posteriori" Probability

The familiar formula of Inverse Probability may be stated as follows:—

Let the probabilities of a number of mutually exclusive causes or conditions $C_1\ C_2 \ldots C_r$ be $P_1\ P_2 \ldots P_r$ respectively, and the probabilities that if $C_1\ C_2$, &c., are realised, an effect or result E will happen be $p_1\ p_2 \ldots p_r$ respectively; then if E happens, the probability that it happened as a result of C_r is

$$\frac{P_r p_r}{\Sigma P p}.$$

The current proofs of this are unsatisfactory, more especially one based on a theorem of James Bernoulli; for even if the ordinary statements of the principle of this theorem were correct, which must be disputed, the argument by which it is applied to Inverse Probability is demonstrably erroneous.

In consequence of the difficulty felt about the usual proofs, there seems to be a tendency to drop the subject, as unsound, out of mathematical theory.

Now it would not be hard to show that there is no essential difference of principle between problems of Inverse Probability and those of ordinary Probability, and therefore it can hardly be doubted that the former should admit of as accurate mathematical treatment as the latter.

The following is offered as a proof which can claim the same rigour as the theorems of ordinary Probability, and illustrates the identity of principle in both kinds of Probability:—

Let A and B be contingencies which are not independent, then by a known theorem

Prob. concurrence of A and B = Prob. A × Prob. of B if A happens.

Or, as it may be shortly expressed,

Prob. A with B = Prob. A × Prob. B if A.

Similarly

Prob. A with B = Prob. B × Prob. A if B.

∴ Prob. A × Prob. B if A = Prob. B × Prob. A if B.

$$\therefore \text{ Prob. A if B} = \frac{\text{Prob. A} \times \text{Prob. B if A}}{\text{Prob. B}};$$

and this is really our theorem. For put $A = C_r$ and $B = E$.

$$\therefore \text{ Prob. } C_r \text{ if } E = \frac{\text{Prob. } C_r \times \text{ Prob. E if } C_r}{\text{Prob. E}}.$$

But Prob. $C_r = P_r$, Prob. E if $C_r = p_r$, and obviously Prob. E $= \Sigma P p$ by a known theorem.

$$\therefore \text{ Prob. } C_r \text{ if } E = \frac{P_r p_r}{\Sigma P p}.$$

Another demonstration may be given which, though a little longer, is quite simple.

If the whole number of "equally likely" cases with reference to a given contingency E is b, and the number of these in favour of E is a, then the mathematical probability of E is, of course, $\frac{a}{b} = p$, suppose.

Considered as a fraction, $p = \frac{na}{nb}$, where n is any quantity whatever.

Suppose n an integer, as a fractional value does not here concern us. We may consider each of the original "equally likely" cases as including n "equally likely" sub-cases; and then we can interpret the fraction $\frac{na}{nb}$ as we interpreted $\frac{a}{b}$, and say that there are nb new cases equally likely, and of these na are in favour of E.

Obviously, if x is the total number of equally likely cases, the number in favour of the event or contingency is px. Again, if q is the probability that E happens if C happens, this means that q of the equally likely cases of C's happening are in favour of

E ; and so, of course, there must be a total number y of such cases such that qy is an integer.

In the problem before us let P_1, P_2, &c., be reduced so as to have a common denominator b, then $P_1 b$, $P_2 b$, &c., are integers.

Multiply in each fraction $P_1 P_2$, &c., numerator and denominator by n, taking n such that $p_1 P_1 nb$, $p_2 P_2 nb$, &c., are integers. Put $nb = x$.

Then of x equally likely cases, $P_r x$ is the number favourable to C_r. And, as above, the number of these again favourable to E, is $p_r P_r x$, that is, the number favourable to E happening as result of C_r (or "C_r if E") $= p_r P_r x$; and the total favourable to E is $\Sigma P p x$.

Now, if the event E happens, the total of possible cases, of which one or other must be the true one, is clearly $\Sigma p P x$, and by hypothesis none of these cases has any preference over the other, and all are "equally likely;" while the number of them favourable to E resulting from C_r is $p_r P_r x$. Therefore the probability if E happens that it happens from C_r is

$$\frac{p_r P_r x}{\Sigma p P}.$$

It may be noticed that a proof of the theorem that if A and B are not independent, Prob. A with B = Prob. A × Prob. B if A, which is repeated in edition after edition of ordinary text-books, and so seems to have passed muster, is, nevertheless, erroneous.

The formula is proved correctly for two independent events, thus :—

Let a be the number of cases in which the first event may happen, b the number of those in which it fails ; a' the number in which the second may happen, and b' the number in which it fails, the cases for each event severally being supposed equally likely. Each of the $(a+b)$ cases may be associated with each of the $(a'+b')$; thus there are $(a+b)(a'+b')$ compound cases which are equally likely. In aa' of these both events happen ; therefore the probability of both happening

$$= \frac{aa'}{(a+b)(a'+b')} = \frac{a}{a+b} \times \frac{a'}{a'+b'} = \text{Prob. first event} \times \text{Prob.}$$
second event.

It is then added that the above proof may be applied to two dependent events, for we have only to suppose that a' is the number of ways in which after the first event has happened the second will follow, and b' the number of ways in which after the first event has happened the second will not follow. Now if this substitution be made in the above, the first step of the proof will be "each of the $(a+b)$ cases may be associated with each of the $(a'+b')$ cases; thus there are $(a+b)(a'+b')$ compound cases which are equally likely." But this is impossible. Each of the $(a'+b')$ cases is one in which the first event happens, and therefore none of them can be associated with any of the b cases, because these presuppose that the first event has not happened. The $(a'+b')$ cases, in fact, can only be associated with the a cases out of the $(a+b)$, and thus the total number of the compound cases intended is not $(a'+b')(a+b)$. A proof can easily be given on the lines already indicated.

If P_1, p_1, n, and b have the same meanings as before, the whole number of equally likely cases is nb, the part favourable to the first event is $P_1 nb$, and the part of these favourable to the second is $p_1 P_1 nb$ (as above shown), which is therefore the number favourable to the concurrence of the two events. The probability, therefore, of the concurrence is

$$\frac{p_1 P_1 nb}{nb} = p_1 P_1$$

Certain confusions which often arise in the statement and application of the mathematical theory of probability would be avoided if a clear idea were formed of what is exactly meant by the fraction which is said to represent the probability of an event.

A good statement of the ordinary account of it is given in Todhunter's Algebra : "If an event may happen in a ways and fail in b ways, and all these ways are equally likely to occur, the probability of its happening is $\frac{a}{a+b}$, and the probability of its failing is $\frac{b}{a+b}$. This may be regarded as a definition of the meaning of the word probability in mathematical works."

A definition must not assume and use the notion to be defined. Here probability is defined through cases "equally likely to occur" ; but "equally likely to occur" means equally probable, and so the definition assumes the very notion which causes difficulty, the notion of "probability" or likelihood, and of which we require the explanation.

The first thing to settle is the meaning of these "equally likely" cases. Is the equal likelihood a quality in things themselves, or is it something in our minds only? If it is a quality in things it can only mean equal possibility of occurrence or realisation. But if a number of cases, mutually exclusive as intended in the above definition, were in the nature of things equally possible, not one of them could happen. If the claim of any one of them in reality were satisfied, so must the claim of any other, since these claims are equal, and therefore if one happens all must, but by hypothesis if one happens no other can ; thus the only possible alternative is that none of them can happen. (It is precisely on this principle that we decide that the resultant of two equal forces at a point, whose directions include an angle, cannot be in any other direction than the bisector of the angle, and that there can be no resultant of two equal forces which act in opposite directions).

The equal likelihood then intended cannot be anything in the nature of things because it is assumed that one of the equally likely cases will happen. It is really only in our minds, when there is an equal balance of reasons for and against two or more events, and due solely to our ignorance, since if we knew which was to happen there could be no such balance and indecision. This is clear if we consider what is the reason why we pronounce one event more likely or probable than another ; it is because we think there is more evidence in favour of the one than in favour of the other, however the "more" may happen to be measured. Two events are equally likely to us when we know nothing more in favour of the one than we do of the other—when the state of our knowledge and (it is important to add) of our ignorance, is the same for both contingencies. This view agrees with the actual procedure in mathematical examples. If a bag contains n balls, and one is to be drawn "at random," there are said to be n equally likely cases, that is, each of the n balls is equally likely to be drawn. Clearly this only means that as we don't know how the hand is going into the bag, we have no information in favour of the drawing of any one ball as compared with any other, and no information against the drawing of any one ball as compared with any other.

"Equally likely" cases then being such that owing to our ignorance the evidence in favour of any one is no greater or less than the evidence in favour of any other, the meaning of the definition of probability above criticised is evident; it is not a definition of probability, but it is the definition of a certain way of measuring evidence.

We are entitled to say that one event is more probable than another when the evidence before us, being decisive for neither, that in favour of the one seems to us, according to some standard of measurement, greater than the evidence for the other. Now what the mathematical analysis does is not to alter the ordinary meaning of "probability" at all, but to find a standard for the measurement of the more and less in evidence.

The whole possibility before us in any given contingency is divided into a number of cases, "equally likely" or "equally possible," in the sense that they are equal from the point of view of the evidence in favour of each of them ; then if one event has more of these equal possibilities in its favour than another, it has in this sense "more" evidence in its favour, and so in accordance with the usual meaning (as above described) of "more probable," is more probable than the other. And here the "more or less" in the evidence is not a mere "more or less," but has a definite numerical measure. The evidence being, so to speak, divided into equal units, the strength of the evidence in favour of a contingency is measured by the number of these units in its favour. Thus if the total of equal possibilities, one of which must happen, for the events A B and C is n, of which a involve A, b involve B and c involve C, the comparative strength of the evidence in favour of A, B and C respectively is measured by the ratios $a : b : c$, while the strength of the evidence of A, B and C respectively, as compared with the evidence for one or other of them happening (which is certain), is, on the same principle, measured by the ratios $\frac{a}{n}$, $\frac{b}{n}$ and $\frac{c}{n}$.

If, then, we symbolise the strength of the evidence for A, B and C by $\frac{a}{n}$, $\frac{b}{n}$, and $\frac{c}{n}$, and similarly that for one or other

of them happening by $\frac{n}{n} = 1$, these quantities have to one another the ratios required. We then arrive at the true meaning of the fraction which is said in mathematics to be the "probability" of a contingency; and much confusion might be avoided if we called the fraction, not the "probability," but the "*modulus of the evidence*," and the so-called equally likely cases not "equally likely" but "*equi-evidential*," or by some more convenient name conveying the same idea.

But it must be insisted that the above is only one way of measuring the evidence, and is not applicable to all cases. Indeed, the more important matters of daily life usually do not admit of it, for there are qualitative differences in strength of evidence which cannot really be measured quantitatively, and that is why the application of mathematical probability to the testimony of witnesses is so obviously futile.

The solution of every mathematical problem in probability is in the last resort only the finding of a modulus of evidence, in the ratio of the part of the whole number of equi-evidential cases which involve a given contingency, to the whole number of such cases; and with the finding of the modulus the strictly mathematical work ends. Mathematics, as such, has nothing to do with the inclination in our minds to expect the event for which the modulus of evidence is greatest (or "the probability" greatest), or the inclination, when some practical step has to be taken, to act on the hypothesis that the event will happen for which the evidence to us seems strong.

Unfortunately, however, there is too often a tendency to confuse the mathematical measure of the mere state of our minds with the measure of something in reality; and this produces various mistakes—*e.g.* the inclination to expect that the actual proportion of the occurrences of the event will tend to conform to the proportion represented by the mathematical probability, *i.e.* conform to a formula of our ignorance. This is an insidious fallacy, and we are not unlikely to fall into it in one form when we have escaped it in another; the mistake of supposing the mathematical probability could be confirmed by actual observation belongs to the head. The attempt to regulate betting by mathematical probability is another instance of the fallacy of confusing the subjective with the objective. The truth is that an observed average may be made the basis of a mathematical "probability" or modulus of evidence, by a process which could easily be explained; but though a "probability" may be based on an average, an average can never be based on a "probability." J. COOK WILSON.

Instruments of Precision at the Paris Exhibition.

I WAS glad to see your appreciative article upon the German instruments of precision at the Paris Exhibition, in which you refer, among other things, to the splendid catalogue which was freely given away to any one who showed any interest and desired to have a copy.

As a member of the Jury of Class 15, I naturally was led to duly appreciate both the German productions and their catalogue, and fearing that this valuable record might too soon become inaccessible, I asked Dr. Drosten if he would send a copy to the Science Library of the Victoria and Albert Museum, so that it might be permanently available for many who might wish to see it. This he most willingly did.

If copies are becoming scarce, it would be more to the point that public libraries attached to scientific institutions should have them than that they should run the risk of being buried and lost in private hands. C. V. BOYS.

A New Form of Coherer.

DURING the past eighteen months I have been called upon to demonstrate the principles of wireless telegraphy in connection with my regular lecture courses, and now and then, while wireless telegraphy was still the latest scientific novelty, in popular lectures.

For the latter purpose it was necessary to have the receiving apparatus as simple as was possible, compatible with a moderate sensibility and regularity of action.

I found the Marconi arrangement, consisting of the separate instruments, coherer, relay and decohering devices, to have the disadvantage, for my purpose at least, of requiring long and careful adjustment each time the apparatus was set up.

It occurred to me that if the functions of the three instruments could be performed by a single instrument, an easier adjustment would result.

This would, perhaps, be of no advantage in the case of a permanent set up, but would be of considerable advantage in apparatus designed for the purpose of demonstration.

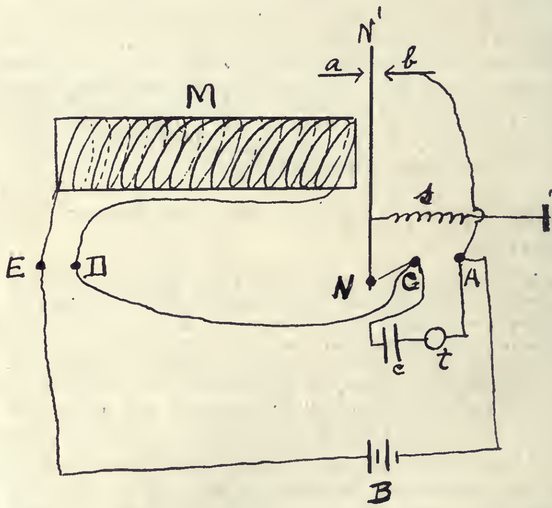
By a slight modification, which need not be permanent, an ordinary telegraph relay of moderate sensibility may be made to serve the purpose of the coherer, relay and decoherer of the Marconi arrangement.

The ordinary telegraph relay is shown in the accompanying sketch.

M is the electromagnet, which in most cases is mounted so that its distance from the armature, NN′, can be varied by a slow-motion screw, E and D are the main circuit terminals, A and C the terminals of the relay circuit, C is connected with the armature NN′, and A is connected to the stop *a* when the instrument is used as a relay. T is a screw connected to NN′ by a spiral by means of which the pressure of the armature on the stop *b* may be varied.

Usually the stop *b* is of hard rubber, and *a* and *b* may be interchanged. If this interchange is made and if C is connected with D, then the battery B will send a current through the electromagnet M and the loose contact N′*b*.

The tension in the spiral, *s*, and the position of the electromagnet may be adjusted so that no current flows, on account of the very high resistance of the loose contact (coherer) N′*b*. If this resistance is lowered by electromagnetic radiations, then the



current through the electromagnet rises and NN′ is attracted towards M and the circuit at N′*b* is broken. The spiral *s* draws NN′ back into contact with *b* and the instrument is ready to again respond to electromagnetic radiations. The adjustment of M and T are easily made, and once made the coherer works very steadily.

The motion of NN′ is too slight to be visible or to close an auxiliary circuit with a sounder, but if a telephone, *t*, in series with a condenser, *c*, is put in parallel with the coherer (*i.e.* across A C) the make and break of N′*b* are clearly audible.

If a "loud-speaking" telephone or a telephone with a manometric flame are used, the make and break can be made audible or visible to an audience.

If the distance between sending and receiving stations should make it necessary, C can be earthed and A connected with a vertical wire. It is well to have the resistance of the electromagnet as low as is compatible with moderate sensibility in order that the normal high resistance of the coherer shall form the major part of the total resistance in series with the battery.

In adjusting the contact N′*b* it is convenient to set M and T so that the armature NN′ vibrates automatically, and then relieve the tension in the spiral *s* until the automatic vibration just ceases.

When this adjustment is made, a "dot" signal from the sending station gives a single "tick" in the telephone—a dash gives a series of ticks.

I have never attempted to telegraph over a distance exceeding

several hundred feet, using the form of coherer described, and, therefore, I am unable to compare its sensibility with that of the usual form.

Undoubtedly it would prove to be less sensitive, but for use over a moderate distance it forms a convenient instrument for the purpose of demonstration. AUGUSTUS TROWBRIDGE.

University of Wisconsin, U.S.A.

Secondary Sexual Characters and the Coloration of the Prong-buck.

THE weak spot in Mr. Cunningham's argument (NATURE, November 8, p. 29) lies in his believing it to be conceded that secondary sexual characters which are the outcome of male katabolism need no explanation by the theory of sexual or of natural selection. Starting with this assumption, he points out that, since these characters are often not developed, male katabolism does not exist in such cases, or exists without producing any visible effects. He therefore rejects male katabolism as the cause of the variations and introduces in its stead "nervous and muscular activity" and "the habits of life and external conditions.

Whether Mr. Cunningham's hypothesis is an improvement upon that of Geddes and Thomson or Wallace may be doubted; and, so far as his views are intelligible to me from the brief epitome his letter contains, they labour under the disadvantage of involving an acceptance in the Lamarckian doctrine and the transmission of acquired characters—problems which, seductive and important though they be, are as yet insufficiently supported by evidence and, whether true or false, stand aside from the Darwinian theory, neither refuting nor confirming it.

After all, "male katabolism," "metabolism" and "physiological activities" are in this connection merely names assigned to the unknown primary cause of certain male characters, and, as such, are nothing but imposing substitutes for the "vital force" of the pseudoscientific realists.

Setting on one side the question of the initial cause of variation, I am quite unable to agree with Mr. Cunningham that secondary sexual characters may reach a high standard of perfection and be maintained in a state of stability by "physiological processes" without the controlling influences involved in the struggle for existence. Sexual variations, once started, must fall, like other variations, under the influence of external conditions; those which are harmful will be eliminated; those which are beneficial selected and preserved. Therefore, considering the diversity of the conditions under which species live, the needs that have to be satisfied, the enemies that have to be avoided, it is no matter for surprise that, even in the males of closely allied forms, the sexual characters vary in degree of manifestation, are sometimes suppressed, sometimes developed; or, taking the particular case Mr. Cunningham mentions, that the nigrescence of the bull kudu and nilghaie may, as I have suggested, be checked for purposes of concealment in the one and emphasised as an ornament or advertisement in the other.

One or two points in Mr. Cockerell's criticism of a footnote (NATURE, October 15, p. 58) call for comment. His suggestion that Mr. Wallace cites the prong-buck as an instance of recognition-marks in the sense in which these terms were employed in my article is inexact; and his opinion that I completely overlooked the point of a theory I was not discussing is, I can assure him, erroneous. Moreover, in spite of his incredulity, I venture to repeat that the prong-buck, with its white belly and darker upper side, *is* an illustration of Thayer's principle. That its patterns are to be explained exclusively on this principle I did not assert. With regard to Mr. Cockerell's reasons for rejecting the view that the prong-buck is procryptically coloured, I would commend the following facts to his consideration. Zebras and giraffes can be "seen from afar off in herds," they seek "safety in flight," and they have the same "necessity for keeping together when in flight" that the prong-bucks have. Nevertheless, these animals are known to be procryptically coloured, though the fact is by no means always evident to those who "have had the pleasure of seeing them in their native wilds." R. I. POCOCK.

November 18.

A New Race of Musk-Ox.

MR. ROWLAND WARD has on view at his establishment in Piccadilly a mounted adult male and female musk-ox from East Greenland, which differ from the ordinary form in having a large whitish patch on the face, as well as in certain other details of coloration. They may be made the types of a new race, under the name *Ovibos moschatus wardi*. The female was recently exhibited at the Zoological Society. R. LYDEKKER.

Harpenden, December 10.

The Optics of Acuteness of Sight.

IN reference to the letter of Mr. Percival in your issue of November 22 (p. 82), concerning acuteness of vision, it is interesting to determine the power of resolution of the eye considered as a lens merely, according to the well-known rule,

$$\theta=\frac{\lambda}{A}\times 2{\cdot}44.$$

Where θ is the angular diameter subtended at the second nodal point by the first dark ring of the diffraction image of a distant point, A is the aperture of the lens, and λ is the wavelength of the radiations (supposed homogeneous) from the distant point.

Taking A for the eye as 4 mm., and λ as 0·000589 mm. (yellow light) the value $\theta = 1{\cdot}2'$ is obtained.

Hence the diffraction image of a luminous point on the retina may be taken as rather less than 1′ in angular diameter (the brightness of the diffraction disc rapidly decreasing towards the first dark ring).

It would thus seem that, should any *considerable* superiority of acuteness of vision exist among savages the cause should be looked for in the aperture of the iris, as well as in greater detail of the retina. F. TWYMAN.

54, Haverstock Hill, London, N.W., November 26.

Euclid i. 32 Corr.

WITH reference to Mr. Allman's letter in NATURE of November 29, the following will, I think, be of interest.

In Proclus' (411–485 A.D.) commentary printed at the end of the Editio Princeps of Euclid (Grynaeus-Bâle, 1533 A.D.) these two corollaries are given:—

(1) The sum of the interior angles of any polygon is equal to twice as many right angles as the polygon has sides less two.

(2) The sum of the exterior angles of any polygon is equal to four right angles. STAM. EUMORFOPOULOS.

33, Gloucester Square, Hyde Park, W., December 3.

A PLEA FOR THE STUDY OF THE NATIVE RACES IN SOUTH AFRICA.

IN a recently-published work Dr. P. Topinard makes the statement that ethnography is cultivated in England because it leads to a knowledge of the natives, and thus prepares the means of turning them to account. This distinguished French anthropologist appears to have permitted his dispassionate judgment to have temporarily forsaken him. Alas! ethnography is but little cultivated in this country, and it may be said to be almost entirely neglected by our Government. It was to take away this reproach in some measure, and to seize the present opportunity in South Africa, that led Mr. E. Sidney Hartland, the President of the Folklore Society, to read before the Anthropological Section of the British Association at Bradford a very carefully considered and temperate paper, "On the Imperfection of our Knowledge of the Black Races of the Transvaal and Orange River Colonies."

Mr. Hartland stated that on the pacification of these colonies one of the first problems confronting us would be the management of the native black population. This led to the question, What did we know of the African races of these provinces? It must be confessed that we knew very little. Our hunters had hunted big game through the land; our missionaries had taught the natives; our traders had traded with black and white; our soldiers had fought in the country, and during the last twenty years mining adventurers had exploited the mineral products. None of these, except the missionaries, had had any real interest in the natives; consequently, few of the others had recorded anything of value

concerning them. The records by the missionaries had been for the most part scrappy, and, from a scientific point of view, not to be implicitly trusted. But the blame for this did not rest entirely on the missionaries. The gap which the missionaries found between the savage mind and their own was unexpectedly wide, and this rendered it difficult for them to understand the natives, as well as for the natives to understand them. Moreover, what the missionary learnt of the native manners and customs he did not think it becoming to publish. Moffat had said that a description of these things would not be instructive or edifying. In the interests of science and government, it was much to be regretted that he and other missionaries had taken this view. Later missionaries had given us more information; John Mackenzie and Livingstone's books contained much of value, but were incomplete, and not always exact. One other reason of our defective knowledge of the customs of the black people was that, until the country was settled by the Boers, there was a state of intermittent warfare, which frequently resulted in the extermination of whole tribes.

There was among the various tribes a general similarity of institutions, customs and belief, but this similarity was by no means uniform. In the Umzimkulu district of Kaffraria all additions to, and alterations of, laws were made by the chief and councils at Great Place. Among the Galekas, Fingoes and Basutos, laws could be altered after the fashion familiar to us in England as "Judge-made law." Conservative as the natives were, the fact that there were recognised ways of making changes implied that such changes were effected, and that differences existed. In the matter of theft the punishments inflicted varied among the different tribes. Property stolen from the chief was punished more severely; in Bechuanaland restitution was required to be made. It was also pointed out that there were difficult questions respecting marriage and inheritance. The prohibited degrees seemed to be in one direction much wider than with us. In general throughout South Africa all blood relationship, which was recognised as such, was an absolute bar to marriage. Among one tribe such a marriage was dissolved, and a heavy penalty inflicted on the man. Among another tribe the only question was how much the man was willing to pay. Some tribes permitted a man to be married to two sisters, both living. Most of the tribes were polygamists. This fact rendered family arrangements very complex, and most of the questions coming before the courts were questions of inheritance. Wives of a native polygamist were not equal in rank. There was a great wife and a right hand wife, and most of the tribes recognised a left hand wife. Among few tribes could a woman inherit property. The Basutos were among the few. In general women, though not themselves property, were in a state of tutelage, and so incapable of either holding or inheriting property. It was easy to understand that the large number of tribes in South Africa would furnish an interminable example of difference of custom. Cases of theft often came before the courts; in some districts cases of inheritance were very common; while cases relating to marriage were always important, because status and inheritance depended on marriage, and such questions were frequent subjects of judicial decision.

One of the modes of oppression of natives in the Transvaal, Mr. Hartland proceeded to observe, had been the refusal to recognise any of their marriages. This was a policy we should be compelled to reverse. In order to do so we must start by informing ourselves what marriages were regarded by the natives of each tribe as legal, lest in our hasty zeal for justice we inflicted injustice. This information could only be obtained by careful inquiry on the spot. A bride-price was usually paid for the bride, but it was not always given. In nearly all tribes, however, it was a necessary incident of the most honourable form of marriage. A bride for whom no price had been paid felt very much as in this country a strict Churchwoman would feel if she were forced to be married at a registrar's office. A wife for whom no price had been paid would be reminded of the fact every time she quarrelled with her neighbours or with one of her fellow-wives, or even with her husband. Twenty years ago the Cape Government came to the conclusion that it ought, both for legislative and administrative purposes, to learn something about the native customs and institutions. The report of that Commission was perhaps the most valuable document we possessed on the black races of South Africa, and must form the basis of any inquiry our Government might make into the customs of the native races of the Transvaal and the Orange River Colony. One of the difficult problems discussed by the Commission was that of the bride-price, known as *Lobola* or *Ukulobola*, and the question was whether the transaction was a bargain and sale of the bride, and, therefore, according to our law, immoral, or, if not, what it was? A Church missionary of twenty-three years' experience described it as being the "direct sale of the girl in its purest state," and a Wesleyan minister said it was the "root of heathenism." On the other hand, Archdeacon Waters and Dr. Calloway, Bishop of St. John's, had, however, expressed their opinion in favour of the custom, holding that the payment was a pledge for the good treatment of the woman, and a pledge of her good conduct.

It was established by the Commission that the custom of *lobola* was not a purchase of the bride, but a substantial guarantee for her good conduct and good treatment. But the inquiry showed that Europeans, even if experienced in native ways, were often incapable, from prejudice or ignorance, of penetrating below the surface to the real meaning of a custom. Some who gave evidence could not distinguish between slavery and tutelage, and in their view every Roman matron would have been a slave.

It must be remembered that we could not civilise the savage all at once, and with a veneer of civilisation he would be more dangerous than before, for he would accept only its sweets and reject its bitters. The subject of beliefs was not less important than that of customs. We ought to govern the native races according to their own laws, and not by ours. We should remember that if we had so much difficulty in understanding their laws, it was no wonder they had similar difficulty in understanding ours. They were, as a missionary told the Commission, so much attached to their customs, and their customs were so much a part of themselves, that they could not imagine any others. An accurate study of the native customs, institutions and beliefs was an urgent necessity both for missionaries and for purposes of government.

Now that the natives had come under British rule the opportunity ought to be taken to register their condition at the time, not less for scientific than for administrative reasons. The happiness of the natives depended on the way we treated them, and if we were ever to raise them to civilisation—which it must be the great object of every civilised Government to do—we must bear in mind that that could only be done gradually, and by deferring, as far as practicable, to their prejudices, and leading them gently, but gradually, from savagery to that condition of life in which we found our happiness, and in which it was to be hoped they would find theirs.

It is to be hoped that Mr. Hartland's plea will not be ignored by Her Majesty's Government, but that as soon as the condition of the Transvaal and the Orange River Colony should permit, and prior to any legislation affecting the natives, a commission should be appointed to

inquire (*a*) into the customs and institutions of the natives of those States, and (*b*) into the relations between the natives and European settlers, with power to make recommendations for the purposes above referred to; such commission to consist, so far as possible, of persons familiar with native life in South Africa, and, in addition, of at least one person, unconnected with South Africa, of recognised eminence in the study of savage customs and superstitions in general. A. C. HADDON.

ZOOLOGY IN THE WEST INDIES.

WE called attention in our "Notes" of November 29 (NATURE, vol. lxiii. p. 112) to a rumour that the curator of the museum of the Institute of Jamaica, who for close upon six years has laboured with marked success, is about to relinquish his office in the spring; and the receipt of confirmatory evidence forces upon us a comment upon the situation. The gentleman in question was originally appointed in 1896 for a period of three years, which was renewed in 1899, and during the whole time he has been most assiduous in both the ordinary curatorial and the scientific duties of his office. Under his charge the collections have grown, and by the renewal of old exhibits, and the incorporation of new ones, with a thorough rearrangement of the whole, they have become so materially improved and attractive as to have merited the cordial approval of expert visitors from the home countries and the United States of America. In pure science he has done more; for, while his predecessors were largely content with the mere superficial study of insects, birds and molluscs, he, covering a wider field, has done admirable work in both zoology and anthropology—in the study of the resources of the surrounding sea and of the aboriginal remains on land. He has produced a series of memoirs on the indigenous sea-anemones and coral organisms, which rank high in contemporary zoological literature, and which, as will be evident from the brief *résumé* of his results, which we published in the afore-mentioned note, have done much to clear up a great deal that is perplexing in the study of these organisms. When it is added that the work has necessitated his journeying afield, and that the climatic conditions render research of the kind on modern lines especially difficult, his threatened removal becomes still more mysterious.

Necessity for retrenchment is the alleged cause of it, and by that we presume is meant desire for relief from taxation. If so, the action does not tally with the fact that but a few weeks ago we received, from an authoritative source, a request for advice upon a scheme based on the belief that it might be possible ere long to obtain laboratory accommodation for marine biological work in the Island, in connection with the erection of some hospital buildings in course of construction. The later intelligence which reaches us indicates a sudden change of front for which we desire explanation. To dispense with the services of a curator would be to waste the labours of years, and to bring into reproach an institution now becoming universally recognised as a centre of enlightenment and culture.

From reports to hand, a suspicion arises that the zoological work, as at present carried out under the auspices of the Institute, is not deemed sufficiently economic or adapted to the precise requirements of the island; and that the failure of a recent attempt, on the part of the Caribbean Sea Fisheries' Development Syndicate, to test the resources of certain shallows and banks in the neighbouring seas by means of trawls and long lines, may have had something to do with the situation. If this be so, we can only express our surprise, for both the area explored and the methods employed were wholly inadequate. Assuming the economic desire, we would point out that the curator of the Jamaica Museum has been by no means neglectful of that phase of his opportunities, and that having recently been commissioned to report upon the Edible Echinus or "sea-egg" of the Barbadoes, in his reply—an *interim* report, now in circulation—he wisely advocates the determination of its life-history and recourse to artificial propagation and restocking.

Assuming that mere impecuniosity is the real cause of the trouble, we would recommend an appeal to the Home Government and the Colonial Secretary for immediate relief; and the advisability of an affiliation of the establishment with either the recently founded Imperial Agricultural Department, of which the headquarters are at the Barbadoes, or with some other existing institution of an authoritative kind. The time has passed at which work in marine zoology can longer be left to the caprice of mere local administration, and persons content only with an immediate *quid pro quo*. Experience shows that the scant success which has attended some of the marine zoological work of the past has been due to lack of coordination in observation. What we require for the future, and to ensure that success which even the economist desires, is more, and not fewer, marine observatories, and that these shall be so placed that collective work, properly coordinated, shall be possible over wide areas. Not until every colony having a sea-board, and till at appropriate points round every coast-line there shall be employed a marine zoologist who is a fishery expert, and who shall be provided with a laboratory, a steamboat, a full set of apparatus, and, if possible, a couple of trained assistants, can the desired result be hoped for. We want, and must have, marine stations at all desirable places, and to discourage one already in the making and doing good work is but to court failure and lessen the only chance of success.

As for the Colonies and their marine zoological and museum work, we would fain see the several existing establishments devoted to these placed under the advisorship of the authorities of the British Museum of Natural History, in the manner in which those in botany have so long been under the guidance of the officials at Kew, subject to their power of appeal to the Home Government; and we feel assured that were this already the case the action we herein deplore would never have come about.

Nearly eight years ago zoologists at home, headed by Huxley, directed attention to the resources of the West Indian seas and the pressing necessity for their investigation; and the work which has emanated from the museum of the Jamaica Institute has largely realised their expectations. The curator of that museum, moreover, during the period he has held office, has cultivated a healthy alliance with the authorities of the Johns Hopkins University and the members of its Biological School, foremost among marine zoologists of the North Atlantic, and this has already been productive of mutual gain and cooperative work in the intervening ocean. We now know that materials of prime importance abound in the Jamaica sea, and in the curator of the Jamaica Museum there lives a man, now familiar with these, competent to investigate with advantage both their scientific and economic aspects. His work, upon which we have commented, has been performed with the fullest sympathy and support of the Board of Governors of the institution. His retirement would be followed by their resignation, and chaos would ensue. The proposal to abandon the curatorship of the museum of the Jamaica Institute is retrogade, and it must not be if we, the proud colonisers of the world, are to retain our prestige.

NOTES.

The retirement of Mr. Charles Whitehead from the position of the Technical Adviser to the Board of Agriculture has led to a reconsideration of the means by which the Board obtain technical advice on questions relating to agricultural botany and economic zoology, and it has now been arranged that the scientific and expert assistance required by the Board in connection with these subjects will be furnished respectively by the Royal Botanic Gardens, Kew, and by the Natural History Departments, South Kensington.

The Paris correspondent of the *Times* states that at the sitting of the Academy of Sciences on Monday M. Becquerel, whose father and grandfather were also men of science, was warmly congratulated on having received the Rumford medal of the Royal Society. The Academy also elected, by forty-six votes to ten, M. Painlevé in the section of geometry to the seat left vacant by M. Darboux.

Dr. Allan Macfadyen, director of the Jenner Institute, has been elected Fullerian professor of physiology at the Royal Institution.

By a decision of the House of Lords, the Institution of Civil Engineers has been exempted from payment of the Corporation Tax (1894). In view of this fact it is submitted that the Royal Colleges of Physicians in London and Edinburgh may reasonably claim similar treatment; and we learn from the political notes in the *Times* that an attempt is being made by Sir John Tuke to induce the Chancellor of the Exchequer to concur in this view. The especial hardship in this case is that, notwithstanding the important part played by the two colleges in administering and regulating medical education and examination, and in maintaining laboratories for original research, and the obligation upon each Fellow to pay a stamp duty of 25*l.* on election, there will be five years of arrears to make up if the authorities persist in their intention to levy the tax.

The following are among the lecture arrangements at the Royal Institution, before Easter:—Sir Robert Ball, six lectures (adapted to young people) on great chapters from the book of nature; Prof. J. A. Ewing, six lectures on practical mechanics (experimentally treated); Dr. Allan Macfadyen, four lectures on the cell as the unit of life; Dr. Arthur Willey, three lectures on the origin of vertebrate animals; the Right Hon. Lord Rayleigh, six lectures on sound and vibrations. The Friday Evening Meetings will begin on January 18, when a discourse will be delivered by Prof. Dewar on gases at the beginning and end of the century. Succeeding discourses will probably be given by Prof. G. H. Bryan, Prof. J. J. Thomson, Sir W. Roberts-Austen, Mr. W. A. Shenstone, Dr. Horace Brown, and others.

Twenty-three papers, several of them of a highly important character, were read at a meeting of the U.S. National Academy of Sciences, held at Brown University, on November 13–14. Among novel subjects of general scientific interest brought before the meeting we notice the following:—An account of the study of growing crystals by instantaneous microphotography, by Prof. T. W. Richards; stereographic projection and some of its possibilities from a graphical standpoint, by Prof. S. L. Penfield; report of progress made with the Echelon spectroscope, and the spectrum of sodium in a magnetic field, by A. A. Michelson; the explanation of inertia and gravitation by means of electrical phenomena, by Prof. H. A. Rowland; male preponderance (Androrhopy) in Lepidopterous insects, by A. S. Packard; exhibition of certain novel apparatus; a wave machine; an expansion lens; a recording system of two degrees of freedom; a tube showing coloured cloudy condensation, by Dr. C. Barus; recent observations of the planet Eros, by Prof. E. C. Pickering.

Some valuable additions have recently been made to the equipment of the observatory of Salò, in Lombardy. They include several recording meteorological instruments, different forms of seismoscopes, a great seismometrograph, and a limnograph for registering the seiches in Lake Gardo, the observatory being situated on its western shore.

A double explosion, resulting in the loss of three lives, occurred on November 28 at the Smokeless Powder Works at Trimley, near Ipswich; the first in the mixing house, where 125 pounds of explosive material were being prepared, and the second in the drying house, which contained a large quantity of gun-cotton. The entire factory, consisting of a series of isolated sheds and a boiler house, was almost razed to the ground, the *débris* being scattered over the adjoining fields. The concussion was felt at Ipswich and Rendlesham House, near Wickham Market, which are about eight and twelve miles respectively from the scene of the disaster, and also, it is said, at other places outside a radius of fifteen miles.

The seismological observatory of Quarto-Castello, near Florence, is one of the most completely furnished so far as regards apparatus provided with mechanical means of registration (see Nature, vol. lxii., p. 200). Several instruments have been added during the past year, and the older ones have received some improvements in detail. Mr. D. R. Stiattesi, the director of the observatory, has just printed his second seismographic bulletin, that for the year November 1, 1899, to October 31, 1900. This valuable pamphlet contains details of the records by the different instruments of no fewer than 135 earthquakes. Its publication within a month of the date of the last entry is a feature worthy of imitation. Dr. G. Pacher has also issued the second part of the seismographic bulletin of the University of Padua for March 19 to June 30, 1899. The records at this observatory are obtained by means of the microseismographs designed by Prof. G. Vicentini, more than half (sixteen out of twenty-nine) being those which are characteristic of distant shocks.

In our Norwegian contemporary, *Naturen*, published in Bergen, Dr. Hans Reusch, director of the Geological Survey, notices some geological investigations of great interest which have been made by a young scientific Icelander, Mr. Helgi Pjetursson. According to this observer, Iceland shows that the Glacial period has had several subdivisions separated from each other by ice-free periods, as has been demonstrated to be the case in the Alps and other similar regions.

Dr. Reusch draws attention in *Naturen* to the changes of level that have taken place in Iceland in recent geological times, viz., since the Ice age. He points out that on a hydrographic map of the North Atlantic Ocean there is shown a submarine ridge under shallow water, which stretches from the Faroe Isles to Iceland and thence over to Greenland. North and north-east of it lies the deep Norwegian Sea. During the Norwegian Atlantic expedition there were found, strewed over the bottom, shells of Arctic mollusca, which at present live in a considerably colder climate and in much shallower water than that which prevails in the Norwegian Sea. Mr. H. Friele directed attention to that fact, and he suggested that the shells had been carried out to the deep sea by drifting ice. It ought, at the same time, to be remembered that Prof. G. O. Sars had found, off the Romsdal coast, in very deep water, shallow water shells and rolled pebbles, and he inferred that this was evidence that sinking of the sea-bottom had taken place there. In 1896 the Danish Ingolf Expedition investigated the sea-bottom between Ian Mayen and Iceland. In examining the dredged material, Herr A. S. Iensen made the observation that almost everywhere over the bottom of the deep ocean lie shells of dead molluscs of well-known

shallow water forms side by side with deep water forms. It was very remarkable to dredge up, from depths of 500 to 1300 fathoms, *Yoldia arctica*, which now lives at Spitsbergen and in the Kara Sea at depths from 5 to 100 fathoms. Dr. Reusch suggests that these remains of Arctic life-forms cannot have been carried there by drifting ice, but that the sea-bottom, in comparatively recent times, during the Ice age, must have been much nearer the sea-level than now. At that time the Arctic shallow water forms must have lived there *in situ*, then a sinking of the sea-bottom has taken place which can be estimated at not less than about 2500 metres. It is easy to see that these results of the Danish naturalist have an important bearing upon the phenomena of the Ice age.

ELECTRO-CHEMICAL sciences and industries will shortly have their own technical journal. The *Electro-Chemist and Metallurgist* will make its appearance on January 15, 1901, and will do its best to keep chemists and manufacturers informed as to the progress of knowledge of electro-chemistry and practical developments. The journal will be published monthly by Messrs. Sherard Cowper-Coles and Co., Ltd., Westminster.

A MONTHLY record of the progress of anthropological science is about to be established by the Anthropological Institute, and will appear under the title of *Man*. Its contents will include contributions to physical anthropology, ethnography and psychology; the study of language, and the earlier stages of civilisation, industry and art; and the history of social institutions and of moral and religious ideas. These various branches of study will be treated more fully, in proportion as they are less adequately provided for in existing periodicals. Special note will be taken, throughout, of investigations which deal with the origins and the earlier stages of those forms of civilisation which have eventually become dominant, and of the races among which they have arisen and developed.

AT a meeting of the Scientific Committee of the Royal Horticultural Society, on December 4, a curious "Weeping Chrysanthemum" was shown. The plant was one of eleven seedlings from a cross raised by Mr. Austen, Ditting Court, Maidstone. The peculiarity of all eleven plants consisted in the downward geotropic direction of the branches, which were bent like those of a Weeping Ash, but upturned heliotropically at the ends, where flowers are produced. Dr. Masters showed a drawing of seedlings of Leucodendron raised by him and presenting a curious outgrowth from the caulicle (hypocotyl), similar to that in the Pea.

THE U.S. *Monthly Weather Review* for July last contains an interesting article on fog studies on Mount Tamalpais, a little to the north of San Francisco, by Mr. A. G. McAdie. The paper is accompanied by photographic illustrations of (1) fog over the Golden Gate, taken from the Weather Bureau Observatory on the above mountain; (2) fog streaming in from the Pacific; and (3) valley fog, originally sea fog, but augmented by radiation about sunset. The locality is well chosen for the study of the formation of fog; from May until September, during which time scarcely any rain falls, great banks of fog invade San Francisco with clock-like regularity every afternoon, while it is known that at some 1500 feet above the air is clear, and 20° or 30° warmer. The mean relative humidity on the mountain is 59 per cent., while at San Francisco it is 83 per cent. It is worthy of note that during the summer of 1899 a difference of temperature of 44° was recorded within so short a distance as 25 miles between Mount Tamalpais (the warmer station) and Point Reyes. The Weather Bureau maintains a regular fog service at San Francisco, and the extent and character of the fog in the roadstead and neighbouring localities are made known by means of frequent reports.

WE have received a copy of the Report of the Meteorological Commission of the Cape of Good Hope for the year 1899. There have been in operation during the year (or some part of it) about 450 stations, including the observatories at the Cape and at Kenilworth, near Kimberley; of this number 364 stations observe rainfall only. About 23 per cent. of the returns are incomplete, owing chiefly to the effects of the war. The observer at Kenilworth (Mr. Sutton) continued his observations all through the siege of Kimberley, although this station was situated outside the lines of defence, and, owing to his courage, the important records for the year are unbroken. It has been found that the old pattern Stevenson thermometer screen formerly used in this country does not sufficiently protect the instruments from the intense radiation in that part of the world, and that, except during strong winds, any two spots inside the screen seldom had the same temperature. The screen adopted is an enlarged one, designed by Mr. C. L. Wragge; it is, like the new pattern Stevenson screen, provided with a double roof, with three overlapping boards in the base of the screen, and it appears to be much better adapted to the conditions prevailing in South Africa. Some interesting notes from the Report of inspection of the stations are given by Mr. C. Stewart, Secretary to the Commission.

IN the annual report of the Imperial Bacteriologist of India (Mr. Lingard) for 1899–1900, we regret to learn that a large portion of the valuable laboratory specimens, records and library was destroyed by fire last year. An outbreak of a disease clinically resembling glanders, but differing from the latter (*a*) in not reacting with mallein, and (*b*) in the absence of the *Bacillus mallei*, is described and identified as "lymphangitis epizootica" of Rivolta, due to a protozoon parasite. The greater portion of the report deals with experiments conducted with regard to rinderpest. Animals vaccinated by injections of blood and of bile of diseased beasts were found to be fully protected nearly two years after the inoculations. Animals may be inoculated with increasing amounts of virulent blood, and then yield a serum which will protect against rinderpest, and a rapid method of immunising is described. The immunity produced by an injection of serum is, however, transient; and in order to produce a lasting or "active" immunity, recourse must be had to inoculation with virulent blood. But this is a risky operation, a considerable proportion of the beasts so inoculated dying; and, in order to avoid this, a preliminary injection of the immunising serum is given followed by the virulent blood. The amount of the serum used must be small, sufficient to ward off serious symptoms but not to prevent a transient illness; otherwise the immunity would be "passive," and not a lasting one.

A NOTABLE instance of "discontinuous distribution" is recorded by Prof. W. M. Wheeler in the *American Naturalist* for November. It appears that in 1886 a very remarkable and aberrant arachnid was described from Sicily under the name of *Koenenia mirabilis*; this creature showing a superficial resemblance to the whip-scorpions, although representing an entirely distinct group by itself. During the past spring Prof. Wheeler collected in Texas an arachnid which, on examination, proved to be specifically identical with the Sicilian form. In Sicily, Koenenia was found in association with species of the genera Japyx, Campodea, Scolopendra, and Pauropus; and, with the exception of the last, it occurs in Texas in company with representatives of the same genera. The European and American species of these genera are, however, distinct. Prof. Wheeler cannot admit that the Koenenia was introduced, and he regards it as the survivor of a very ancient fauna. An analogous case is presented by the occurrence of *Proiapyx stylifer*, a primitive thysanurid insect, in Liberia and Argentina.

IN the *American Naturalist* Prof. Wheeler describes a new genus of insect living commensally with certain ants. The general reader will, however, be specially interested in the so-called "mushroom gardens" formed by the ants in question. It appears that they cut and transport into their subterranean cellars large pieces of leaves, which are there divided into smaller fragments, and ultimately reduced to a fine pulp. "This pulp is heaped up, and soon becomes invaded by the mycelium of a fungus. The mycelium is kept aseptically clean—*i.e.* free from all species of fungi and even from bacteria—and induced to grow in an abnormal way by bringing forth minute swellings which constitute the only food of the ant colony. Möller likens these swellings to the 'kohlrabi' of the German kitchen gardens."

THE U.S. Department of Agriculture has published a *Bulletin*, by Dr. L. O. Howard, describing the principal insects affecting the tobacco plant. Although indigenous to America, this plant does not suffer so severely from insect attacks as do many other crops in the United States. It has no insect enemies peculiar to itself, although every year a certain amount of damage is done to the crop, which in some seasons may assume serious proportions. Remedial agencies in the form of poisons can be easily applied to the seed-beds, while arsenical spray may be employed at a later stage. Much good can also be effected by means of various solanaceous plants, such as nightshade, horse-nettle, and Datura, growing in the neighbourhood of the crop. Small clumps of these can be left growing, which will attract the noxious insects while the tobacco is still young, such clumps being subsequently cut down and destroyed with the pests upon them.

THE Trustees of the Indian Museum have issued a "Guide to the Zoological Collections exhibited in the Bird Gallery," by Mr. F. Finn. The author is so well known as an authority on Indian birds that any contribution from his pen on the subject cannot fail to be of value. But he has departed from the usual practice of ornithologists by relegating the groups generally termed "orders" to the rank of "suborders," thereby rendering avian classification much more in harmony with that of other vertebrate classes. He also refrains from adding the superfluous affix "*formes*" to such subordinal groups. While in every respect admirably suited to the special purpose for which it is intended, this "Guide" has, therefore, a value considerably exceeding that attaching to the majority of publications of a similar nature.

WE have received Parts vii. and viii. of "Papers from the Harriman Alaska Expedition," now in course of publication in the *Proceedings* of the Washington Academy of Sciences. Both are from the pen of Mr. T. Kincaid, and deal with entomology. Although the collection of insects and arachnids is very large indeed, it indicates that, with the possible exception of the beetles, which were previously collected during the Russian occupation, scarcely a beginning has been made towards bringing to light the arthropod fauna of this vast region. Mr. Kincaid commences with an account of the insects known as Tenthredinoidea, of which he describes a number of new forms. His second communication deals with the metamorphoses of certain beetles.

IN an article on Lepidoptera in South Devonshire, which appears in the December issue of the *Entomologist*, Mr. J. Jäger states that he never saw the clouded yellow butterfly in such profusion as in the week following August 15. They were simply swarming in the clover fields and lanes, and were probably as numerous as in 1877. Two plates of hybrid moths illustrate the continuation of the account of experiments on cross-breeding by Prof. Max Standfuss in the same issue.

AMONG other papers, the November issue of the *Journal* of the Quekett Microscopical Club contains one by Mr. A. A. Merlin, on "Structural Division of the Endoderm in Bacilli of the Bubonic Plague," which ought to prove of considerable interest to students of that disease at the present time.

THE December number of the *Entomologist's Monthly Magazine* contains a communication from Baron C. R. v. d. Osten Sacken, in which it is pointed out that the proper title of the malaria-producing mosquito is *Anopheles maculipennis*, and not, as has been generally supposed, *A. claviger*.

THE distinctive peculiarities of the skull of the puma forms the subject of a note by Dr. A. Dugés in the last issue of the *Memorias y Revista* de la Sociedad Cientifica "Antonio Alzate."

THE Anthropological Society of Paris has just published an authors' and subject index of all publications issued by it since its foundation in 1860.

MESSRS. A. GALLENKAMP AND CO. have issued a bulky and comprehensive catalogue of chemical apparatus, balances and accessories of various kinds used in the teaching of chemistry and related subjects and in practical analysis. The catalogue is one which may with advantage be kept for reference by science demonstrators and teachers.

THE third edition, revised and enlarged, of "An Elementary Treatise on Dynamics, containing Applications to Thermodynamics," by Dr. B. Williamson, F.R.S., and Dr. F. A. Tarleton, has been published by Messrs. Longmans, Green and Co. The whole work has been revised and some portions of the subject have been developed, more especially that on generalised co-ordinates in connection with Lagrange's and Hamilton's methods. Students intending to devote serious attention to the study of dynamics will find the volume a helpful introduction to the great treatises of Thomson and Tait and of Routh.

AN elaborate "Report on the Census of Cuba," by Lieut.-Colonel J. P. Sanger (Director) and Messrs. H. Gannett and W. F. Willcox (Statistical Experts), has just been published by the U.S. War Department. The census was the first step taken towards the establishment of an effective system of self-government in the island, and as no census had previously been taken by the people the difficulties were numerous and great. To induce the Cubans to take a real interest in the census, it was decided that the work should be performed by them, under the supervision of an officer of the United States Census, and this was actually done, so that when the enumeration was completed it was a census of Cubans by Cubans. The total population of Cuba, including the Isle of Pines and the neighbouring islets, was 1,572,797 on October 16, 1899. At a census taken under Spanish authority in 1887, the population was returned as 1,631,687, and if this is assumed to be correct, the diminution during the twelve intervening years is about 3·6 per cent. The native whites constitute 57·8 per cent., or considerably more than one-half of the population of Cuba; the foreign white people constitute 9 per cent.; the coloured people 32 per cent., or about one-third; and the remainder are Chinese. Illustrations of typical Cuban people and buildings, and numerous maps are included in the report.

READERS of popular periodicals know that articles upon scientific topics appear in every number of *Pearson's Magazine*. The December number contains several contributions of this character. The Rev. H. N. Hutchinson describes some prehistoric animals and illustrates them with some good pictures. Special mention is made of the giant ground sloth of Patagonia, for a living representative of which Mr. H. Prichard is seeking, having been sent to Patagonia for this purpose by the *Daily Express*. A number of striking coloured portraits of American Indians, showing the devices painted upon their faces, as marks

of distinction, accompany an article by Mr. T. Dreiser. The marble quarries at Monte Sagro, in the vicinity of Carrara, are described and illustrated by Mr. E. St. John Hart. Two series of photographs of a cat and dog jumping over an obstacle are contributed by Mr. A. C. Banfield. Dr. See's views upon the mode of formation of stellar systems are expounded in another article. Mr. George Griffith describes the line where the day changes, near the 180th degree of longitude, making it the text of an article upon the places where the twentieth century will commence; and Mr. Walter Wellman describes some of his Arctic experiences. Six pretty photographs of birds are reproduced in the *English Illustrated Magazine.*

THE use of gas thermometers at high temperatures is the subject of an interesting paper by Messrs. Holborn and Day (*Wied. Ann.* 68, 817). Experiments with porcelain vessels, glazed and unglazed, have shown that this material is unsuitable for the construction of the containing vessel, especially when the gas used is hydrogen. Platinum iridium vessels (10 or 20 per cent. Ir) containing nitrogen appear to be very trustworthy; after the thermometer has been heated to 1100° C. for a considerable time, the indications of the instrument at low temperatures remain unaltered. The thermo-elements usually employed for the measurement of high temperatures have been carefully compared with this gas thermometer, and the electromotive force represented as a quadratic function of the temperature. With these thermo-elements the melting-points of a series of metals have been determined, so that the calibration and control of other elements is made independent of the standard nitrogen thermometer. The authors claim that the error in the determination of high temperatures (up to 1150° C.) does not exceed 1° C. The influence of air on the melting-points of copper and silver is interesting, as is evident from the following numbers—copper (pure) 1084·1° C., (in air) 1064·9° C.; silver (pure) 961·5° C., (in air) 955° C.

WE learn from the Marine Biological Laboratory at Plymouth that a male specimen of *Squilla desmarestii*, 2⅝ inches long, was brought in last week by a shrimper who had been trawling inside Plymouth Breakwater. The rarity of this Stomatopod in Devonshire waters is shown by the fact that this is only the second specimen that has been taken at Plymouth since the laboratory opened in 1888, the other, a small one ½-inch long, having been taken in the tow-net about three years ago.

THE additions to the Zoological Society's Gardens during the past week include two Puff Adders (*Bitis arietans*), a Yellow Cobra (*Naia flava*), two Delalande's Lizards (*Nucras delalandii*), thirty-two Spotted Slow Skinks (*Acontias meleagris*), three Rough-keeled Snakes (*Dasypeltis scabra*) three Smooth-bellied Snakes (*Homalosoma lutrix*), three Crossed Snakes (*Psammophis crucifer*), five Rhomb-marked Snakes (*Trimerorhinus rhombeatus*), two Coppery Snakes (*Prosymna sundevalli*), a Lineated Snake (*Boodon lineatus*) from South Africa, presented by Mr. J. E. Matcham; six Yellow-legged Frogs (*Rappia horstockii*) from South Africa, presented by Mr. W. L. Sclater; a Black Rat (*Mus rattus*), British, presented by Mr. E. Wormold; two Bactrian Camels (*Camelus bactrianus*, ♂ ♀) from Siberia, a Moose (*Alces machlis*, ♂) from North America, two Ashy-black Macaques (*Macacus ocreatus*) from the East Indies, a Golden-headed Marmoset (*Midas chrysomelas*) from South-east Brazil, a Red-footed Lemur (*Lemur rufipes*) from Madagascar, a Rufous-necked Wallaby (*Macropus ruficollis*) from New South Wales, four Westerman's Eclectus (*Eclectus westermani*) from Moluccas, a Plain-coloured Amazon (*Chrysotis inornata*) from South America, a Mongolian Pheasant (*Phasianus mongolicus*, ♂) from Mongolia, a Blackbird (*Turdus merula*, pied. var.), European, deposited.

OUR ASTRONOMICAL COLUMN.

LOCAL CONDITIONS FOR OBSERVATION OF THE TOTAL SOLAR ECLIPSE, 1901, MAY 17–18.—A pamphlet has been received containing information for observing parties and summaries of the climatological conditions along the track of the moon's shadow during the total solar eclipse in May 1901. The work is the report of a committee of the society, Koninklijke Natuurkundige Vereeniging in Nederlandsch-Indië, appointed at the request of the Government at Batavia.

With the exception of Batavia, which is out of the eclipse track, there is no regular meteorological service in the Malay Archipelago. Regular observations of rainfall, however, have been made during the period 1879–1900 at about 220 different places. As this factor alone does not give sufficient evidence as to the suitability of a place for observation of a total solar eclipse at noon, special series of climatic data have been obtained during the months of April, May and June 1900, in several places well situated for the purpose.

Twenty-two stations have been selected, extending from Padang, on the west coast of Sumatra, to Amboyna and Saparua, at the eastern extremity of the Celebes group. Tables are given showing the cloudiness of the sky, mean rainfall, daily and hourly rainfall.

As regards general condition of sky during May, the west coast of Sumatra appears to have the worst reputation, the percentage clearness being only 28 per cent., as against 50 per cent. for the Macasar Sea between Borneo and Celebes.

As regards rainfall, the western stations are apparently the better, Padang averaging fifteen rainy days in May, while at Amboyna there are twenty-seven. The actual rainfall is little or no indication of weather condition, as excessive rains do not involve a period of clouded sky; on the contrary, the atmosphere is cleared from dust by heavy rains, so that in the rainy season the sky is much more transparent than during the dry season. Several suggestions with respect to the accommodation at the various localities may be useful to observers.

The most convenient stations will probably be on the west coast of Sumatra. *Padang* is the residence of the Governor, is in weekly communication with Europe, has a telegraph office and four hotels.

Painan is situated south of Padang on the sea shore; it has no harbour, but is easily reached by land from Trusan Bay, where there is good anchorage.

Solok, in the interior, at an elevation of 1300 feet above sea-level, has a telegraph office and small hotel, and is connected with Padang by rail.

Pulo Lalang, an islet of the Lingga group, lies close to the central line, and possesses good anchorage for small vessels, which could be hired at Singapore.

Pontianak, on the west coast of Borneo, is in direct communication with Singapore once or twice weekly. It has a small hotel. The soil is said to be very swampy and unsuitable for large instruments.

Macasar, the capital of Celebes, has a telegraph office and two hotels, and is in direct communication with Singapore once a week.

Amboyna and *Saparua* are only in communication once or twice a month unless with special service.

As soon as a station is selected, arrangements should be made for securing the support of the civil officials, application being made in the first instance to the Governors or Residents. For temporary establishments bamboo and other materials are obtainable on the spot, and are inexpensive. Skilful craftsmen are not available except in the principal places. Portland cement may be purchased at Padang, Batavia, Surabaya and Macasar. No Customs duties are levied on instruments in the Dutch Colonies.

"ANNUAIRE ASTRONOMIQUE, &C., FOR 1901."—This well-known little annual volume, which is compiled by M. Camille Flammarion, will be found as useful as ever for the coming year. One finds in it all the more important details and events of celestial phenomena. Thus, we are given the facts about the coming solar and lunar eclipses, the chief tables of the solar system, charts of the sky for each month, showing the paths and positions of the planets. Further, there are several short notices on such subjects as solar spots, atmospheric observations, the eclipse of 1900, meteor observations, terrestrial magnetism, meteorological tables, &c. As a handy *vade mecum* for those who possess and use small equatorials, this annual should be specially very welcome.

"THE HEAVENS AT A GLANCE," 1901.—This handy little publication (now in its fifth year of issue) is practically a card calendar devoted to astronomical particulars, and is designed to serve as a handy remembrancer as to the phenomena predicted for any period, any further details required being obtained from a more bulky volume of reference. Besides the daily phenomena of importance, monthly summaries of the aspects of constellations, sun's declination, moon's phases, and positions of planets are given. This occupies about half of the sheet. The remainder is devoted to a series of useful descriptive notes and statistics of various celestial objects, including special features on the moon's terminator during the lunation, elongations and oppositions of the planets, data for eclipses, meteor shower radiants, and the coordinates of a selection of the brightest stars. This card should be especially useful to amateurs who find the larger reference books too cumbersome. It may be obtained from the compiler, Mr. Arthur Mee, F.R.A.S., Tremynfa, Llanishen, near Cardiff.

"COMPANION TO THE OBSERVATORY" FOR 1901.—This useful contribution to the astronomer's library has recently been issued, and will doubtless be accorded its usual welcome. The contents, occupying 36 pages, have from experience been so condensed as to leave out no information likely to be wanted by the general worker that little or no alteration has been made in the arrangement. Beginning with particulars of the sun's times of rising, setting, its declination, mean and sidereal time, and phases of the moon for every week, there follows a calendar showing the times of rising, southing and setting of the moon, and the longitude of the terminator for each day of the year; a list of the principal radiant points of meteors, compiled by Mr. Denning; ephemerides for all the planets, including the minor planets Ceres, Pallas and Vesta; and times of elongation, stationary points, &c.; solar and lunar eclipses, occultations; phenomena of the satellites of Mars, Jupiter, Saturn, Uranus and Neptune; ephemeris containing data for physical observations of the sun; mean places of variable stars, with epochs of maxima and minima; particulars of 115 double stars.

ARGON AND ITS COMPANIONS.[1]

THE discovery of krypton and neon was announced to the Royal Society in the early summer of 1898; and subsequently atmospheric air was found to contain a heavier gas to which the name of xenon was applied. Mr. Baly, in the autumn of the same year, called attention to the presence of helium lines in the spectrum of neon, an observation which confirms that made by Prof. Kayser, of Bonn, and by Dr. Friedländer, of Berlin.

At the same time we imagined that we had obtained a gas with a spectrum differing from that of argon and yet of approximately the same density; to this gas we gave the name metargon. It has now been found that the presence of the so-called metargon is to be accounted for by the fact that in removing oxygen from the mixture of these gases, which was then in our hands, phosphorus containing carbon was employed; this mixture when burned in oxygen yields a spectrum to some extent identical with that furnished by carbon monoxide, but differing from it inasmuch as lines of cyanogen are also present. We have no doubt that the so-called metargon, the spectrum of which is visible only at high pressure, and only when impure phosphorus has been employed to remove oxygen, must be attributed to some carbon compound. In spite of numerous experiments we have not yet succeeded in producing any gas in quantity which yields this composite spectrum. It is only to be obtained by a mixture of carbon monoxide with cyanogen.

To obtain the heavier gases krypton and xenon, a large amount of air was allowed to evaporate quietly; the residue was freed from oxygen and nitrogen, and then consisted of a mixture of krypton, xenon and argon, the last forming by far the largest portion of the gas; this mixture was liquefied by causing it to flow into a bulb immersed in liquid air, and the bulk of the argon was removed as soon as the temperature rose, the krypton and the xenon being left behind. By many repetitions of this process we were finally successful in separating these three gases from each other. While krypton has a considerable vapour-pressure at the temperature of boiling air, the vapour-pressure of xenon is hardly appreciable, and this afforded a means of finally separating these two gases from one another; in the complete paper the operations necessary to separate them are fully described.

For neon the process of preparation was different. The air liquefier furnished a supply of liquid air; the gas escaping from the liquefier consisted largely of nitrogen; this mixture was liquefied in a bulb immersed in the liquid air which the machine was making. When the bulb had been filled with liquid nitrogen a current of air was blown through the liquid until some of the gas had evaporated. That gas was collected separately, and deprived of oxygen by passage over red-hot copper; it contained the main portion of the neon and the helium present in the air. The remainder of the nitrogen was added to the liquid air used for cooling the bulb in which the nitrogen was condensed. Having obtained a considerable quantity of this light nitrogen it was purified from that gas in the usual manner, and the argon containing helium and neon was liquefied. By fractional distillation it was possible to remove the greater portion of the helium and neon from this mixture of gases, leaving the argon behind. Many attempts were made to separate the helium from the neon. Among these was fractional solution in oxygen, followed by a systematic diffusion of the two gases; but it was not found possible to raise the density of the neon beyond the number 9·16, and its spectrum still showed helium lines. It was not until liquid hydrogen, made by an apparatus designed and built by one of us (M. W. T.), had been produced in quantity, that the separation was effected; the neon was liquefied or perhaps solidified at a temperature of boiling hydrogen, while the helium remained gaseous. A few fractionations serve to produce pure neon; we did not attempt to separate the helium in a pure state from this mixture.

That these are all monatomic gases was proved by determination of the ratio of their specific heats by Kundt's method; the physical properties which we have determined are the refractivities, the densities and the compressibilities at two temperatures, and of argon, krypton and xenon the vapour-pressures and the volumes of the liquids at their boiling points.

The results are as follows:—

	Helium.	Neon.	Argon.	Krypton.	Xenon.
Refractivities (Air = 1) ...	0·1238	0·2345	0·968	1·449	2·364
Densities of Gases (O = 16)	1·98	9·97	19·96	40·88	64
Boiling-points at 760 mm.	?	?	86·9° abs.	121·33° abs.	163·9° abs.
Critical temperatures ...	?	below 68° abs.	155·6° abs.	210·5° abs.	287·7° abs.
Critical pressures	?	?	40·2 metres	41·24 metres	43·5 metres
Vapour-pressure ratio ...	?	?	0·0350	0·0467	0·0675
Weight of 1 c.c. of liquid	?	?	1·212 grammes	2·155 grammes	3·52 grammes
Molecular volumes	?	?	32·92	37·84	36·40

The compressibilities of these gases also show interesting features. They were measured at two temperatures—11·2° and 237·3°; the value of P.V. for an ideal and perfect gas at 11·2° is 17,710 metre-cubic-centimetres, and at 237·3° to 31,800. This is, of course, on the assumption that the product remains constant whatever be the variation in pressure. Now with hydrogen at 11·2° C. the product increases with the rise of pressure; with nitrogen, according to Amagat, it first decreases slightly and then increases slightly. With helium the increase is more rapid than with hydrogen; with argon there is first a considerable decrease followed at very high pressures by a gentle increase, although the product does not reach the theoretical value at 100 atmospheres pressure; with krypton the change with rise of pressure is a still more marked decrease, and with xenon the decrease is very sudden. At the higher

[1] A paper by Prof. William Ramsay, F.R.S., and Dr. Morris W. Travers. Read at the Royal Society on November 15.

temperature the results are more difficult to interpret; while nitrogen maintains its nearly constant value for P.V., helium decreases rapidly, then increases, and the same peculiarity is to be remarked with the other gases, although they do not give the product of P.V. coinciding with that calculable by assuming that the increase of P.V. is proportional to the rise of absolute temperature.

These last experiments must be taken as merely preliminary; but they show that further research in this direction would be productive of interesting results.

The spectra of these gases have been accurately measured by Mr. E. C. C. Baly, with a Rowland's grating; the results of his measurements will shortly be published. It may be remarked, however, that the colour of a neon-tube is extremely brilliant and of an orange-pink hue; it resembles nothing so much as a flame; and it is characterised by a multitude of intense orange and yellow lines; that of krypton is pale violet; and that of xenon is sky-blue. The paper contains plates showing the most brilliant lines of the visible spectrum.

That the gases form a series in the periodic table, between that of fluorine and that of sodium, is proved by three lines of argument:—

(1) The ratio between their specific heats at constant pressure and constant volume is 1·66.

(2) If the densities be regarded as identical with the atomic weights, as in the case with diatomic gases such as hydrogen, oxygen and nitrogen, there is no place for these elements in the periodic table. The group of elements which includes them is:—

Hydrogen. 1	Helium. 4	Lithium. 7	Beryllium. 9
Fluorine. 18	Neon. 20	Sodium. 23	Magnesium. 24
Chlorine. 35·5	Argon. 40	Potassium. 39	Calcium. 40
Bromine. 80	Krypton. 82	Rubidium. 85	Strontium. 87
Iodine. 127	Xenon. 128	Cæsium. 133	Barium. 137

(For arguments in favour of placing hydrogen at the head of the fluorine group of elements, see Orme Masson, *Chem. News*, vol. lxxiii., 1896, p. 283).

(3) These elements exhibit gradations in properties such as refractive index, atomic volume, melting-point and boiling-point, which find a fitting place on diagrams showing such periodic relations. Some of these diagrams are reproduced in the original paper. Thus the refractive equivalents are found at the lower apices of the descending curves; the atomic volumes, on the ascending branches, in appropriate positions; and the melting- and boiling-points, like the refractivities, occupy positions at the lower apices.

Although, however, such regularity is to be noticed, similar to that which is found with other elements, we had entertained hopes that the simple nature of the molecules of the inactive gases might have thrown light on the puzzling incongruities of the periodic table. That hope has been disappointed. We have not been able to predict accurately any one of the properties of one of these gases from a knowledge of those of the others; an approximate guess is all that can be made. The conundrum of the periodic table has yet to be solved.

ACTION OF TERRESTRIAL MAGNETISM ON THE RATES OF CHRONOMETERS.

IN the issue of the *Comptes rendus* of the Paris Academy of Sciences for November 26, vol. cxxxi., pp. 859-865, there is an important communication by Prof. A. Cornu, dealing with an experimental investigation of the action of a terrestrial magnetic field on the rate of a magnetised chronometer.

The observations have been carried out on a pocket half-chronometer, provided with anchor-escapement, compensated balance and palladium spiral, whose rate had previously been very satisfactory, but which had inadvertently become magnetised by a large electro-magnet. The generally prevalent idea is that a magnetised watch is quite untrustworthy until it has been completely demagnetised, but the author's research has convinced him that there is evidence of a regular law in the rate of such an affected timepiece, and therefore it should be possible to neutralise the disturbance, either by tables of correction formulæ, or by suitably disposed compensators.

The magnetisable parts are the pivots, anchor, spring, balance-wheel and accessories to the escapement. In watches of precision all direct contacts between steel parts are avoided by the use of hard stone bearings, so that the mutual actions are inductive effects. If, then, the watch be laid on a horizontal table at a definite orientation, the only disturbing external force capable of affecting its rate will be the terrestrial magnetic field. To test this, provision was made for varying the orientation of the balance by making the horizontal support movable about a vertical axis, and then keeping the watch or clock for several days successively in the four positions corresponding to the hours XII, III, VI, IX, pointing respectively to the Magnetic North.

Systematic observations from 1898 June 20 to 1900 November 17, furnish a series of values for the variations in rate at the four orientations, and the discussion of them has enabled Prof. Cornu to show that they may be represented by a *sinusoid*. The magnetic state of the watch remains sensibly constant; the semi-amplitude of the variations with the orientation was 10·37 secs., and the mean azimuth of the ascending node of the sinusoid about 260° 21′. This result is especially interesting and important in that this sinusoidal law is identical with that obtaining when a watch having a balance wheel slightly out of equilibrium is hung with its dial vertical and oriented to different azimuths. That is, gravity also produces, if the mean amplitude remains constant, a couple proportional to the vertical projection of the eccentricity of the centre of gravity. Here a series of observations of the rate of the same watch before it was magnetised are given, taken during the period 1890 October 26–1891 January 25, showing the fulfilment of the sinusoid law in this respect.

It would thus appear that the condition discovered by Phillips (*Annales des Mines*, 6th series, vol. ix., p. 321, 1866) for eliminating the disturbance due to gravitation may also be applied to the compensation for magnetisation.

As a crucial test of the truth of his deductions, Prof. Cornu performed a substitution experiment in which the earth's magnetism was directly allowed for. In a piece of cork of exactly the same form as the watch a cylindrical hole was cut in the position corresponding to the balance wheel. In this was supported a small compass needle, and the whole supported on a horizontal table. By means of a jointed arm a bar magnet was held in such a position that the earth's magnetism was neutralised, leaving the needle astatic. This done, the watch was substituted for the cork, the orientation of the balance wheel being the same as the small compass in the cork. This substitution of cork model, getting astatic position by bar magnet, and replacement of watch, was repeated for the four orientations, and the daily rate carefully determined. It was found to be sensibly *constant in all positions*.

The paper concludes with the following summary:—

(1) Chronometers of precision are influenced by variations of the magnetic field in which they are placed to an amount depending on the degree of magnetisation of the balance wheel and spring.

(2) It is important to determine the magnetic moment of the balance wheel, mounted or not on the spiral.

(3) In observatories studying chronometer rates it is necessary to regularly determine the comparative variations in four rectangular azimuths for calculating the formulæ of correction.

(4) In all cases it should be the endeavour to attain an amplitude of 440° for the oscillations of the balance wheel, as recommended by Phillips, to eliminate the action of the terrestrial magnetic couples.

(5) For precaution, in observatories as well as on board ship, it would be well to envelop each chronometer with a thick box of iron, so that the relative action of the terrestrial field may be lessened.

C. P. B.

THE EFFECTS OF AN EARTHQUAKE ON HUMAN BEINGS.

CAPTAIN DUTTON'S valuable memoir on the Charleston earthquake of 1886 contains many accounts of the effects of this great earthquake on human beings. Nowhere could they be more vivid than in Charleston itself. "On every side," says one witness, "were hurrying forms of men and women, bareheaded, partially dressed, some almost nude [the earthquake

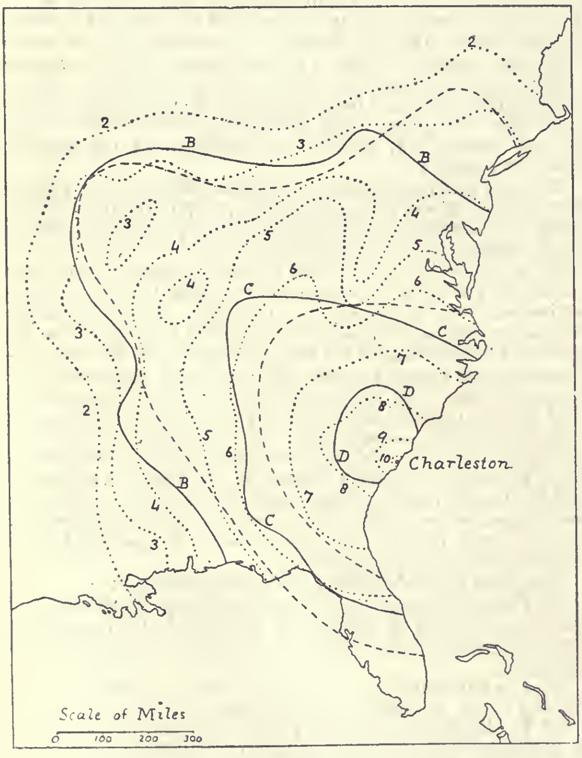
occurred at 9.51 p.m.], and all nearly crazed with fear and excitement. . . . A few steps away, under the gas-lamp, a woman lies prone and motionless on the pavement, with upturned face and outstretched limbs, and the crowd which has now gathered in the street passes her by, none pausing to see whether she is alive or dead . . . ; many voices are speaking at once, but few heed what is said." Between this, which must surely be almost the limit of wild fear in a crowd, and the merely interested curiosity of the most distant observers, there seems to be nearly every stage of mental effect recorded. Such terms as "greatest consternation," "fright and excitement unparalleled," and "terror amounting to wild frenzy," are, of course, too dependent on the narrator and too vague to be of any value as degrees in a scale of mental effects; but the resulting actions are less liable to error or exaggeration, and these may be roughly classified as follows, the different degrees being lettered to avoid confusion with the numbers of the soseismal lines:

(A) No persons leave their rooms.

(B) Some persons leave their houses.

(C) Most persons run into the streets, which are full of excited people.

(D) People rush wildly for open spaces, and remain all night out of doors.



In the third degree of the scale, I included at first the hasty dispersal of meetings; but, when the places at which this occurred are plotted on a map, it is evident that this effect would find an appropriate place under the second heading. A crowd in one room is more liable to excitement and fear than are persons in separate houses.

In the accompanying map, the dotted curves are the isoseismal lines as drawn by Captain Dutton. The continuous curves bound the areas in which the effects corresponding to the three higher degrees of the scale were observed. The curve for the first degree of course coincides with the outermost isoseismal line.

It will be seen that there is a certain rough agreement between these curves and the isoseismal lines. The curve D and the isoseismal 8 are not far apart; in other words, if the shock was strong enough to throw down chimneys or make cracks in the walls of buildings, then people thought it wiser to camp out for the night. The curve C and the isoseismal 6 coincide approximately; that is, people rushed precipitately into the streets if the movement made chandeliers, pictures, &c., swing. On the whole, the curve B roughly follows the isoseismal 3; so that, if the shock was not even strong enough to cause doors and windows to rattle, some persons were so alarmed that they left their houses, and public meetings were dispersed. Whether these effects were due to the rarity of the phenomenon or to the highly-strung nerves of the American people, it may, I think, be inferred that in no other civilised country would such alarm be shown at a sudden and unexpected occurrence.

Captain Dutton also gives many records of a feeling of nausea at the time of the earthquake; and, however excitable the observers may have been, these accounts are probably trustworthy, for this is not at all generally known to be a result of earthquake-motion. I have marked these places on a map, and it is curious that, with one or two exceptions, they all lie between the two broken lines of the figure. The most distant places at which the feeling was noticed are Blue Mountain Creek (New York), 823 miles, and Dubuque (Iowa), 886 miles, from Charleston. The outer boundary of the nausea area follows roughly the curve B, but is generally inside it; the inner boundary is so close to the curve C as to suggest that there may be some connection between them, that, in the wild hurry to reach the street, the slight feeling of nausea might escape notice.

CHARLES DAVISON.

THE CAMBRIDGE SENTINEL MILK STERILISER.

THIS is a simple and automatic milk steriliser for domestic use. It is made in three forms; in one, which is intended for use on an ordinary fire, a tube which carries an alarm bell at the top is inserted through the lid of the saucepan. When the desired temperature (85° C.) is reached, a trigger contained in the tube is automatically released, and the bell rings, thus warning the attendant to take the pan off the fire. In a second form the action is automatic. A saucepan containing the sensitive trigger is placed on a gas stove, and when the proper temperature is reached the release of the trigger causes the supply of gas to be automatically cut off. A third form is arranged for use with a spirit lamp. In each case, the automatic mechanism is actuated through the melting of an easily fusible alloy.

For the apparatus it is claimed (1) that it is simple and works automatically, (2) that the temperature (85° C.) attained does not impair the flavour or the nutritive qualities of the milk, (3) that injurious micro-organisms, including tubercle, are destroyed. Dealing with these claims in order, the apparatus certainly acts automatically and seems to be of simple construction. With regard to the first or bell form, however, the sound of the bell is so slightly audible that it would certainly be missed unless the attendant were listening for it, and in all probability in nine cases out of ten the milk would be boiled. The second form, with gas stove and automatic cut-off, works quite well and is much to be preferred. With regard to the temperature at which the signal is given or the cut-off takes place there is some difference, according to the amount of fluid which is being treated. Dealing with the two-pint size we have observed the following temperatures:

		Bell Form.	Cut-off Form.
Water	Half pint	94° and 95° C.	95° and 93° C.
	One pint	87·5° ,, 89°	86° ,, 87°
	Two pints	87° ,, 86°	84° ,, 85°
Milk	Half pint	98° (frothing)	95°
	Two pints	87°	84°

It will thus be seen that there is a considerable variation in the temperatures.

As to the second point, we consider that the temperature of 85° C. is too high, and we believe that the experiments of Duclaux and others have conclusively shown that milk cannot be heated above 70° C. without altering its flavour and nutritive qualities. Tested practically, milk heated in the apparatus and immediately cooled has a pronounced flavour, little less marked than milk which has been just boiled and then cooled. Three samples—(1) untreated, (2) sterilised in the apparatus and immediately cooled, (3) boiled and cooled—were submitted to three individuals, who separately tasted them; two of the individuals were unable to distinguish between the sterilised and boiled samples; the third said "that the sterilised sample seemed a little less boiled than the other." The flavour being so markedly altered, we doubt whether the claim that the nutritive qualities of the milk are unchanged can be substantiated.

The temperature 85° C. was probably chosen because it may be relied upon with certainty to kill pathogenic organisms, especially the tubercle bacillus. We believe, however, that a temperature of 65° C., acting for twenty minutes, is sufficient to kill the tubercle bacillus, and that, therefore, pasteurised milk, *i.e.*, milk heated to 68° C. for twenty minutes, is quite safe, and certainly its flavour is almost unaltered. We are aware, of course, that some observers claim that tuberculous milk may retain its infective properties after pasteurisation, but the work of Theobald Smith seems to explain the contradictory results which have been obtained. He found that tubercle bacilli suspended in water, saline solution, bouillon or milk were destroyed at 60° C. in 15—20 minntes. If, however, a pellicle forms on the milk, then the tubercle bacilli in the pellicle seem to be protected, and may survive an hour's heating at 60° C. (*Journ. Exper. Med.*, iv, 2, p. 217).

NEW SYNTHESES OF SOME DIUREIDES.

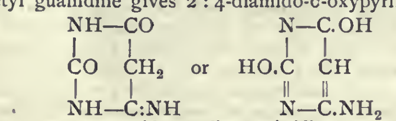
W. TRAUBE publishes in the present number of the *Berichte* further details on the new syntheses of uric acid, xanthine and the methyl derivatives of the latter—theobromine, theophylline and caffeine. The starting point is either cyanacetic acid or its ester. Cyanacetic acid and urea in presence of phosphorus oxychloride form cyanacetyl urea,

$$NH_2.CO.NH.CO.CH_2CN.$$

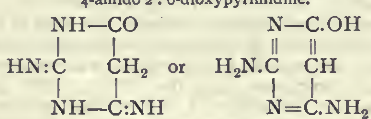
Also cyanacetic ester and guanidine combine with the separation of alcohol, forming cyanacetyl guanidine,

$$NH_2C(:NH).NH.CO.CH_2.CN.$$

The further treatment of these two compounds is similar. With alkalis they are converted into cyclic (pyrimidine) compounds. Cyanacetyl urea forms 4-amido-2 : 6-dioxypyrimidine, whilst cyanacetyl guanidine gives 2 : 4-diamido-6-oxypyrimidine

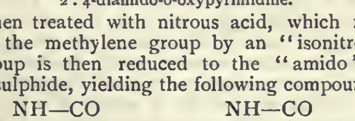


4-amido 2 : 6-dioxypyrimidine.

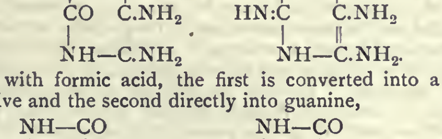


2 : 4-diamido-6-oxypyrimidine.

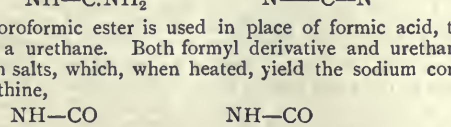
They are then treated with nitrous acid, which replaces the hydrogen of the methylene group by an "isonitroso" group, and this group is then reduced to the "amido" group by ammonium sulphide, yielding the following compounds:



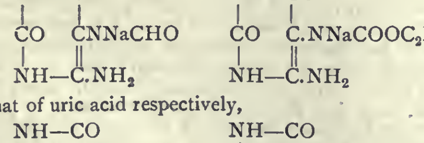
Boiled with formic acid, the first is converted into a formyl derivative and the second directly into guanine,



If chloroformic ester is used in place of formic acid, the first yields a urethane. Both formyl derivative and urethane form sodium salts, which, when heated, yield the sodium compound of xanthine,



and that of uric acid respectively,



Sodium xanthine. Sodium urate.

Guanine may be readily converted by Fischer and Strecker's method into xanthine, and by methylation into theobromine and caffeine, whereas by using methyl urea in the formation of cyanacetyl urea in the first method, or by methylating the formyl compound, theobromine, theophylline, caffeine and the corresponding uric acids may be produced. A patent has been taken out by the discoverer for these processes.

ARTIFICIAL RAIN.[1]

THE question perpetually arises in the popular mind as to whether man cannot produce rain or drought according as his needs may dictate. The possibility of doing this is never questioned by barbarians, who have their professional rain makers and great medicine men, and superstitiously attribute to them all power over nature. In some parts of the Christian world it has been believed that man could bring about rain or drought, not by his own power, but by intercession with the Creator, who would, perhaps, work a miracle on his behalf. During the past thousand years miracles have been confessedly rare, and some consider it almost impious for a man to dare to interfere with the operations of nature on a large scale; some even refuse to be doctored for disease.

The recognition of the truths revealed by modern science has made it evident that man can affect the weather only by understanding and making use of the laws of nature. He must do it in a natural or scientific way, not through any supernatural power or in any miraculous way. In fact, those who have a very imperfect knowledge of the laws of nature, if any at all, are often inclined to believe that there really must be some process known to science, or still to be discovered, by which man can bring abundant rain from the clouds when and where he needs it. They point to the popular belief that rain follows great battles, as proving that there is some way by which to affect the clouds—it may be through the noise of the battle, or it may be the burning of the gunpowder, or it may be a possible electric disturbance. They point to the reputed influence of lightning rods, which are supposed to draw the lightning from the skies and prevent the formation of hail.

In these and other matters there is abundant room for self-deception. It would be a great mistake to conclude that any battle by reason of its noise, or heat, or gunpowder has had any effect in the way of producing rain, or that the lightning rods have had any effect in producing or preventing hail. The statistics that are supposed to substantiate such conclusions do not really prove anything of the kind, and yet many are deceived by them because in reasoning upon the phenomena of nature they forget to apply the simplest laws of logic, and are carried away by emotions or preconceived opinions or the plausible suggestions of others. This is not at all singular, for the history of man's progress in knowledge is the history of a long series of mistakes covering thousands and tens of thousands of years. All have to learn by bitter experience, and if science seems to have made rapid progress during the past century, that should not blind our eyes to the fact that errors may still prevail among the professional men of science as well as the rest of mankind.

In the special matter of the artificial formation of rain we heartily endorse the statement that if it is in any way possible to bring this about we must labour to discover it; in fact, we eventually shall discover the way, if there be one, but thus far nothing has been accomplished to justify us in believing that feasible methods exist or are likely to exist. Various methods have had their advocates both in Europe and America, and the citizens of the United States, with a nervous energy that is greatly to be admired, have given a full and fair trial, at great expense, to several methods advocated by men of imperious natures that would brook no denial short of nature's own experimental demonstration of their errors. Thus the rain-making by explosives was most thoroughly tested by order of Congress at an expense to the public of many thousands of dollars, and the results have been discussed sufficiently, both in public and private, to show that nothing in the way of rain, and probably nothing in the way of cloud or mist, was produced. One of the first experimental trials was made quite near Washington, D. C., at night-time, November 2–3, 1892, when a series of clouds with showers were passing over the neighbouring country, and these continued right along for several hours

[1] Abridged from a contribution by Prof. Cleveland Abbe to the U.S. *Monthly Weather Review*.

quite independent of the bombardment. The reports from numerous observers showed that as the showers moved along over the earth's surface those in front of it reported that the noise of the exploding dynamite occurred just before the shower; those in the wake of the shower reported that the shower came before the explosion, while those in the midst of the shower, of course, heard the explosion while it was raining. There was no evidence that the explosion had any effect on the clouds. Careful observations in Washington, D.C., during the whole of this first experiment, and during subsequent experiments with explosives, warranted the conclusion that no rainfall was produced by bombardment.

About that time a "rain wizard" commenced operating in Ohio. His method consisted in locking himself in a barn, house, luggage van or other room, wherein he made a fire and burned or evaporated certain chemicals, the smoke of which rose through the roof out of some impromptu chimney or stove-pipe and dissipated itself in the thin air. Of course it was claimed that the chemicals exerted a great influence on the atmosphere and forced rain to come. Occasionally rain did come after one, two, or three days of a chemical performance, but equally often it did not come. The Weather Bureau was often importuned for advice as to when the wizard should be called to any given town, and whether the inhabitants would be justified in paying him his fee of several hundred dollars. Eventually, a prominent railway company rigged up a car for his use, and during the years 1892–4 made it convenient for all the citizens on its lines to invoke the aid of "the rain producer." Of course there were numerous cases in which the operations were followed by rain; those who studied the Daily Weather Map could see at a glance that these rains accorded with the general weather conditions and had nothing to do with the rain-making operations. So long as frequent rains occurred, although they were natural and were predicted by the Weather Bureau on the basis of the weather map from day to day, yet the farmers of Iowa, Kansas and Nebraska, ignoring this fact, were sure to accredit all success to the wizard.

During the last great drought in California, 1898–1899, the citizens of one city authorised an extensive and expensive system of experiments by gases and by cannon, but were fortunately saved the necessity of actually wasting their money by the fact that an abundant rain fell naturally just before they were ready to begin their own operations.

Occasionally we still receive newspaper items reviving the old story that floods of rain were broken up by cannonading at Rome, or that rain was produced by cannonading in Italy, or that hailstorms were averted from a special vineyard that was protected by lightning rods while neighbouring vineyards suffered. These are all repetitions of the same old myths, or repetitions of useless experiments, and the intelligent reader may dismiss them as having no foundation. No matter how severely his land may be suffering from drought or flood, he should seek some other mode of relief and not waste his time and money in efforts to change the nature of the clouds or the atmosphere.

ON THE STATISTICAL DYNAMICS OF GAS THEORY AS ILLUSTRATED BY METEOR SWARMS AND OPTICAL RAYS.[1]

IMAGINE a cloud of meteors pursuing an orbit in space under outside attraction—in fact, in any conservative field of force. Let us consider a group of the meteors around a given central one. As they keep together their velocities are nearly the same. When the central meteor has passed into another part of the orbit, the surrounding region containing these same meteors will have altered in shape; it will in fact usually have become much elongated. If we merely count large and small meteors alike, we can define the density of their distribution in space in the neighbourhood of this group; it will be inversely as the volume occupied by them. Now consider their deviations from a mean velocity, say that of the central meteor of the group; we can draw from an origin a vector representing the velocity of each meteor, and the ends of these vectors will mark out a region in the velocity diagram whose shape and volume will represent the character and range of deviation. It results from a very general proposition in dynamics that as the central meteor moves along its path the region occupied by the group of its neighbours multiplied by the corresponding region in their velocity diagram remains constant. Or we may say that the density at the group considered, estimated by mere numbers, not by size, varies during its motion proportionally to the extent of the region on the velocity diagram which corresponds to it.

This is true whether mutual attractions of the meteors are sensibly effective or not; in fact, the generalised form of this proposition, together with a set of similar ones relating to the various partial groups of coordinates and velocity components, forms an equivalent of the fundamental principle of Action which is the unique basis of dynamical theory.

Now, suppose that the mutual attractions are insensible, and that W is the potential of the conservative field: then for a single meteor of mass m and velocity v we have the energy $\frac{1}{2}mv^2+m\mathrm{W}$ conserved: hence if δv_1 be the range of velocity at any point in the initial position, and δv_2 that at the corresponding point in any subsequent position of the group, we have $v_1\delta v_1=v_2\delta v_2$, these positions remaining unvaried and the variation being due to different meteors passing through them. But if $\delta\omega_1$ and $\delta\omega_2$ are the initial and final conical angles of divergence of the velocity vectors, corresponding regions in the velocity diagram are of extents $\delta v_1 . v_1^2\delta\omega_1$ and $\delta v_2 . v_2^2\delta\omega_2$: these quantities are, therefore, in all cases proportional to the densities at the group in its two positions. In our present case of mutual attractions insensible, the volume density is thus proportional to $v\delta\omega$, because $v\delta v$ remains constant. Now the number of meteors that cross per unit time per unit area of a plane at right angles to the path of the central meteor is equal to this density multiplied by v: thus here it remains proportional to $v^2\delta\omega$, as the central meteor moves on. In the corpuscular formulation of geometrical optics this result carries the general law that the concentration in cross-section of a beam of light at different points of its path is proportional to the solid angular divergence of the rays multiplied by the square of the refractive index, which is also directly necessitated by thermodynamic principles; as a special case it limits the possible brightness of images in the well-known way.

In the moving stream of particles we have thus a quantity that is conserved in each group—namely, the ratio of the density at a group to the extent of the region or domain on the velocity diagram which corresponds to it; but this ratio may vary in any way from group to group along the stream, while there is no restriction on the velocities of the various groups. If two streams cross or interpenetrate each other, or interfere in other ways, all this will be upset owing to the collisions. Can we assign a statistical law of distribution of velocities that will remain permanent when streams, which can be thus arranged into nearly homogeneous groups, are crossing each other in all directions, so that we pass to a model of a gas? Maxwell showed that if the number of particles each of which has a total energy E is proportional to $\epsilon^{-h\mathrm{E}}$, where h is some constant (which defines the temperature), while the particles in each group range uniformly, except as regards this factor, with respect to distribution in position and velocity jointly, as above, then this will be the case. In fact, the chance of an encounter for particles of energies E and E′ will involve the product $\epsilon^{-h\mathrm{E}}\epsilon^{-h\mathrm{E}'}$ or $\epsilon^{-h(\mathrm{E}+\mathrm{E}')}$, and an encounter does not alter this total energy E + E′; while the domains or extents of range of two colliding groups each nearly homogeneous and estimated, as above, by deviation from a central particle in position and velocity jointly, will have the same product after the encounter as before by virtue of the Action principle. It follows that the statistical chances of encounter, which depend on this joint product, will be the same in the actual motion as are those of reversed encounter in the same motion statistically reversed. But if the motion of a swarm with velocities fortuitously directed can be thus statistically reversed, recovering its previous statistics, its molecular statistics must have become steady; in fact, we have in such a system just the same distribution of encountering groups in one direction as in the reverse direction: thus we have here one steady state. The same argument, indeed, shows that a distribution, such that the number per unit volume, of particles whose velocity deviations correspond to a given region in the velocity diagram, is proportional to the extent of that region without this factor $\epsilon^{-h\mathrm{E}}$, will also be a steady one. This is the case of equable distribution in each group as regards only the position and velocity diagrams conjointly; but in this case each value of the resultant velocity would occur with a frequency

[1] A paper read by Dr. J. Larmor, F.R.S., before Section A of the British Association at Bradford, September, 1900.

proportional to its square, and a factor such as e^{-hE} is required to keep down very high values. The generalisations by Boltzmann and Maxwell to internal degrees of freedom would lead us too far, the aim here proposed being merely concrete illustration of the very general but purely analytical argument that is fully set forth in the treatises of Watson, Burbury and Boltzmann.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. H. Herbert Smith has been appointed Gilbey lecturer in agriculture for the next three years. Prof. Macalister and Dr. Habershon have been appointed additional examiners for medical degrees.

The Walsingham Gold Medal in biology has been awarded to Mr. H. Dale of Trinity College, and the Bronze Medal to Mr. R. C. Punnett of Caius College.

The University of New Brunswick has been affiliated to the University of Cambridge.

The researches submitted to the Board for physics by Mr. J. B. B. Burke, Mr. W. C. Henderson and Mr. A. H. Peake, advanced students, have been approved as qualifying for the B.A. degree.

Dr. Anningson, Dr. Collingridge, Prof. Sims Woodhead and Dr. Tatham have been appointed examiners in sanitary science.

The proposal for enabling the examiners to award a first class to candidates for the Natural Sciences Tripos, Part II., who show a sufficient knowledge of two subjects, but do not quite attain the first class standard in either, has been rejected by the Senate.

THE Childhood Society offers prizes of two guineas and one guinea for the two best essays on some prescribed subjects referring to the mental and physical characteristics of children. Information can be obtained from the Hon. Secretary of the Society, 72 St. Margaret Street, London, W.

GLANCING through the Calendar of the University College at Nottingham, we notice the announcement that the Board of Education is prepared to pay three-fourths of the laboratory fees at the College of Government teachers engaged in science teaching who wish to become familiar with practical methods. This rule applies to other University Colleges.

SCIENTIFIC SERIALS.

American Journal of Science, November.—Elaboration of the fossil cycads in the Yale Museum, by L. F. Ward. The collection contains twenty-nine different species of cycads from the Black Hills, represented by nearly eight hundred specimens. A number of new species are described, and termed respectively Cycadeoidea superba, rhombica, heliochorea, utopiensis, reticulata, minima, and protea.—Chemical composition of turquoise, by S. L. Penfield. Turquoise is so uniform in its chemical constitution that it can hardly be considered an accidental mixture of an aluminium phosphate and a copper phosphate. Copper and iron must be regarded as constituents rather than impurities. The author derives it from ortho-phosphoric acid, in accordance with the formula

$$[Al(OH)_2, Fe(OH)_2, Cu(OH), H]_3PO_4.$$

—Quartz-muscovite rock from Belmont, Nevada, by J. E. Spurr. The rock described occurs in a large dyke just east of Belmont. It occurs in large masses, changing gradually and irregularly into alaskite or muscovite-biotite granite. It is identical with the "beresite" occurring in the Urals in association with veins of auriferous quartz.—Volumetric estimation of copper as the oxalate, with separation from cadmium, arsenic, tin and zinc, by C. A. Peters. The precipitation of copper oxalate from solutions containing at least 0·0128 grammes of the oxide and saturated with oxalic acid is practically complete. Moderate amounts of copper may be determined quantitatively as the oxalate by precipitation with oxalic acid and titration of the precipitate by potassium permanganate. Copper may also be separated from other metals in the presence of nitric acid by the addition of considerable amounts of oxalic acid.—Synopsis of the collections of invertebrate fossils made by the Princeton expedition to Southern Patagonia, by A. E. Ortmann. Thirty-six new species are described, mostly gastropoda.—The kathode stream and X-light, by W. Rollins. The author advances two arguments against the supposition that the kathode stream particles are always of the same size, move with the same speed, and carry the same charge. Mercury particles appear too heavy to generate X-rays, and the loss of material from kathodes of different metals is not the same.

Bollettino della Società Sismologica Italiana, vol. vi., 1900–1901, No. 4.—The great earthquake of June 12, 1897, by R. D. Oldham. A summary of the author's report on the great Indian earthquake, and of his memoir on the propagation of earthquake motion to great distances (*Phil. Trans.*, 1900A, pp. 135–174).—A new protographic seismic pendulum, by G. Costanzi. A description of an apparatus for recording only the first part of the earthquake-motion, the surface on which the record is made being withdrawn from the moving pendulum.—Principal eruptive phenomena in Sicily and the adjacent islands during the year 1899, by S. Arcidiacono.—Notices of earthquakes recorded in Italy (June 5 to August 4, 1899), by A. Cancani, the most important being the Tuscan earthquake of June 27, the Latian earthquake of July 19, and distant earthquakes on June 5, 14, 17, July 7, 11, 12 and 14.

SOCIETIES AND ACADEMIES.

LONDON.

Linnean Society, November 15.—Mr. C. B. Clarke, Vice-President, in the chair.—Mr. W. B. Hemsley, F.R.S., F.L.S., exhibited a number of specimens and drawings of Fitchia (Hook. f. in *Lond. Journ. Bot.* iv. p. 640, pls. 23, 24), including a new species from the island of Raratonga in the Cook Archipelago, discovered by Mr. T. F. Cheeseman. The genus was described from specimens thought to have been procured on Elizabeth Island, a remote coral island in the Eastern Pacific; but Mr. Hemsley gave reasons for believing that the locality of the plant described by Sir Joseph Hooker was Tubnai Island in the same latitude, but 20° further to the west: an island of volcanic origin and mountainous, and, therefore, more likely than a coral island to be the habitat of such a plant, especially as it was originally discovered by Banks and Solander in Tahiti. Only three or four species are known: they are small resiniferous shrubs of tree-like habit, with rather thick branches, opposite simple leaves borne on slender stalks, and terminal, usually solitary flower-heads. Mr. Hemsley next exhibited an abnormal cluster of fruits of the edible chestnut found by Mr. Charles Read of Sway in the New Forest, and forwarded to Kew by the Rev. J. E. Kelsall. Usually there are two or three, rarely four in a cluster; but in the specimen exhibited there were at least fifteen, the largest nuts measuring about an inch in their greatest diameter. He also exhibited a curious flask-shaped bird's nest, which had been sent to Kew by Mr. J. H. Hart, Director of the Botanic Garden, Trinidad, but without any information concerning the bird which built it. It was constructed almost entirely of the soft plumose seeds of a species of Tillandsia (Bromeliaceæ). It measured a foot in length and between four and five inches in its greatest diameter, and had the entrance at the base, the receptacle for the eggs being near the top of the inside. Mr. J. E. Harting, in reply to a question from the chairman, said that without seeing a specimen of the bird which had built the nest in question, it was not easy to name the species with certainty; but that it was doubtless the nest of an Icterus, and probably of *Icterus leucopteryx*, commonly known in the West Indies as the Banana-bird.—Mr. James Groves, on behalf of Mr. Cecil R. P. Andrews, exhibited specimens of a Sea Lavender new to the Channel Islands, *Statice lychnidifolia*, Girard, discovered by Mr. Andrews in August of the present year growing sparingly on low rocks by the sea in Alderney in company with *S. occidentalis*, the most nearly allied British species. Mr. Groves pointed out that the interest of the record consisted, not so much in the fact of the plant occurring in Alderney (being a native of the adjacent French coast, and the Channel Islands being geographically more French than British), as in the fact that a species should be added to the flora of one of our possessions so near home.—Mr. W. C. Worsdell read a paper entitled "Further Observations on the Cycadaceæ," intended to throw additional light on the problem as to the phylogenetic origin and relationships of this group of plants.—On behalf of Miss Alice L. Embleton a paper was read by Prof. G. B. Howes on

a new entozoic Copepod (*Goidelia echiura*) found together with an Infusorian (*Trichodina*) in the rectum of a new Japanese marine Worm (*Echiurus unicinctus*) recently described by her in the Society's *Transactions*. This Copepod is eyeless, and a description was given of its appendages in both the adult and metamorphic stages, from careful dissections under the microscope made in one of the laboratories of the Royal College of Science.

Geological Society, November 21.—J. J. H. Teall, F.R.S., President, in the chair.—A Monchiquite from Mount Girnar, Junagarh (Kathiawar), by Dr. J. W. Evans. After a brief account of the rocks of the monchiquite-type, in which ferromagnesian silicates are embedded in an isotropic matrix with the chemical constitution of analcime, the author describes an example from Mount Girnar, where it is associated with a nepheline-syenite intrusive in a mica-augite-diorite. The most striking feature of this rock is the occurrence of colourless spheres of various sizes up to about 1 mm. in diameter. The rest of the rock is mainly composed of a hornblende of the barkevikite-type; a pale green augite is also present.—The geology of Mynydd-y-Garn (Anglesey), by Charles A. Matley. Mynydd-y-Garn, a hill of less than 600 feet elevation, stands above the village of Llanfair-y'nghornwy in north-west Anglesey. The mass of the hill is an inlier of sericitic and chloritic phyllites (Garn Phyllites), surmounted by a massive conglomerate (Garn Conglomerate), and surrounded by black slates and shales of apparently Upper Llandeilo age. The general dip of all the rocks is northerly and north-easterly. The Garn Phyllites are usually green altered shales and fine gritty rocks, and are intensely contorted near their southern boundary. Even where not contorted they show under the microscope evidence of powerful earth-movement. They are considered by the author to be part of the "Green Series" of northern Anglesey. They are cut off to the west and south by a curved fault, probably a thrust, which brings them against Llandeilo slates and breccias. The district around Mynydd-y-Garn has been affected since Llandeilo times by two powerful earth-movements, acting one from the north, the other from the north-east. The first-mentioned prevailed in the area west and north-west of the hill, where the pre-Llandeilo rocks are frequently shattered to crush-conglomerates. Around Mynydd-y-Garn itself and east of it the principal direction of movement has been from the north-east; south of the hill the structure is, perhaps, the result of the interference of these two movements.—On some altered tufaceous rhyolitic rocks from Dufton Pike (Westmorland), by Frank Rutley, with analyses by Philip Holland. The specimens described were collected by the late Prof. Green and Mr. G. J. Goodchild from the Borrowdale volcanic series which constitutes the central mass of Dufton Pike, and the chief interest attaching to them is their alteration, probably as the result of solfataric action.

Anthropological Institute, November 22.—Mr. W. Gowland, Vice-President, in the chair.—A paper was read by Messrs. MacIver and Wilkin on their Algerian journey. The main object of the journey was to investigate the evidence for the Libyan origin of Prof. Flinders Petrie's "New Race." The districts especially investigated were the Aurès mountains, inhabited by the Chawia, and Kabylia; and a large number of lantern slides were secured which were exhibited in illustration of the paper. The manufacture of pottery was described in detail; the readers considered that the identity of one entire class of Kabyle ware with that of prehistoric Egypt in respect of colour, technique, and details of ornament, as well as numerous coincidences of form, proved the close culture connection of the ancestors of the Berbers with prehistoric Egypt. Other classes of pottery seemed to have been directly derived from or communicated to Cyprus. Turning to questions of anthropography, the readers showed that the Berbers are essentially a white race with brown-black hair, brown or hazel eyes and a skin which is really red-white. They are, therefore, the true representatives of the white Libyans of the Egyptian wall-paintings. Blondes occur but seldom; they form not more than 10 per cent. The paper concluded with a summary of the results of an anthropometrical examination of a very large series of prehistoric Egyptian and modern Berber skulls; the results showed the two races to be quite distinct. The expedition has strengthened the case for culture connection between Libya and Egypt, but disproved the theory of common race.

November 27.—Mr. C. A. Read, President, in the chair.—Prof. E. B. Tylor communicated, and commented on, a paper by Mr. Paxton Moir on stone implements in Tasmania. The paper described the sites on which the stones were found and the uses to which the various forms were put. The types included knives and hand axes which were fairly common, and also a certain number of concave "scrapers" and pointed "groovers." There was, however, considerable difference of opinion as to the propriety of using a very definite terminology and attributing to the manufacturers very definite intentions where there was obviously very little command over the materials. Another point which roused some discussion was whether the stones were shaped to fit the hand or selected because they were so shaped, or whether the adaptability of the hand did not account for the readiness with which a "grip" was found.—A large number of Tasmanian implements being on the table, the points raised in the discussion received practical illustrations. There were also exhibited, on behalf of Mr. Alfred Sharpe, C.B., H.B.M. Commissioner of Nyassaland, a double clapperless bell, a stone implement of uncertain use, and a wooden stool supported on a carved female figure with prominent keloid scars, and native head-dress, from Angoniland.

Royal Microscopical Society, November 21.—Mr. Wm. Carruthers, F.R.S., President, in the chair.—Mr. Nelson exhibited and described an erect image dissecting microscope by Leitz, and sent for exhibition by Mr. C. Baker. The erection of the microscopic image, effected by means of Porro prisms, was first described by Ahrens in the *Journal* of the Society in 1888. The instrument was valuable as a dissecting microscope; it was provided with handrests and three objectives, having a very long working distance.—Mr. Disney exhibited a diffraction plate having the lines ruled in concentric circles, by which the diffraction bands were separated with great clearness. The rulings were about 7000 to the inch. He also exhibited a steel brooch the surface of which had been ruled in the same way.—Mr. C. F. Rousselet exhibited an electric lamp for use with the microscope.—The president called attention to the exhibition that evening of a number of slides from the Society's cabinet, prepared by the late Dr. Carpenter in connection with his investigations into the shells of the mollusca. Mr. B. B. Woodward also exhibited some preparations.—Prof. Chas. Stewart referred to the views held upon shell structure at the present day, and, taking the common pinna shell as an example, demonstrated how its structure was built up. Besides studying the sections usually made, he recommended that shells should be broken and the fractured surfaces examined, if a correct idea of the formation of the shells was to be obtained.

Zoological Society, December 4.—Dr. Henry Woodward, F.R.S., Vice-President, in the chair.—The Secretary read an extract from a letter which had been addressed to the Colonial Office by the West India Committee, concerning the proposed introduction of the English starling or the Indian mynah into St. Kitts, West Indies, to check the increase of grasshoppers, which were causing great damage to the growing crops in that island.—Mr. R. Lydekker exhibited, on behalf of Mr. Rowland Ward, and made remarks upon the mounted skin of a female musk-ox which had been obtained from East Greenland.—Dr. C. I. Forsyth Major exhibited and made remarks on some remains of *Cyon* from Sardinia, and of a monkey (*Macacus*, sp. inc.) from Mauritius.—Mr. A. H. Cocks made some remarks on the period of gestation of the pine-marten (*Mustela martes*), which he had ascertained could not be less than ninety-four days and might possibly be as much as 106 days.—Mr. J. S. Budgett read a paper on the breeding-habits of *Protopterus*, *Gymnarchus*, and some other West African fishes, in which an account was given of a collecting trip made during last summer to the swamps of the Gambia River in search of the eggs of *Polypterus*. The eggs of *Polypterus* were not discovered, though a very young specimen, measuring only one inch and a quarter in length, was found. In this small specimen the dermal bones were not developed, and the external gills were of very great size, the base of the shaft being situated immediately behind the spiracle. The dorsal finlets formed a continuous dorsal fin. While Mr. Budgett was in search of the eggs of *Polypterus*, the underground nests of *Protopterus annectens* were found in abundance, and complete series of eggs and larvæ were preserved. The male *Protopterus* was found to live in the nest until the larvæ were fit to leave it. Nests were also found of the curious fish *Gymnarchus niloticus*. These were made in

about three feet of water, and floated on the surface. The nest was two feet long and a foot wide; the walls of the nest stood several inches out of the water around two sides and one end. The opposite wall was low, and here was the entrance to the nest. Nests of *Heterotis niloticus*, *Hyperopisus bebe* and *Sarcodaces odoë* were also described.—A series of papers on the collections made during the "Skeat Expedition" to the Malay Peninsula in 1899–1900 was read. Mr. J. Lewis Bonhote reported on the mammals, and enumerated the fifty-four species of which specimens had been obtained. One new species was described as *Mus ciliata*. Mr. N. Annandale gave a short description, illustrated with lantern slides, of the country traversed, and read the notes he had made on the habits and natural surroundings of the insects he had observed. Mr. F. F. Laidlaw gave an account of the frogs collected by himself and Mr. Annandale; they embraced examples of twenty-nine species, of which four, viz. *Rana signata*, *R. Lateralis*, *Bufo jerboa* and *Microhyla inornata*, had not previously been recorded from the Malay Peninsula. The earthworms collected during the expedition were reported upon by Mr. F. E. Beddard, who described from amongst them ten new species belonging to the genus Amyntas.—A communication was read from Dr. Arthur G. Butler containing an account of the butterflies collected by Mr. Richard Crawshay in the Kikuyu Country of British East Africa in the years 1899 and 1900. The species represented in the collection were 116 in number, six of which were described as new in the paper.—Mr. R. Newstead contributed a paper on a new scale-insect (*Walkeriana pertinax*), collected by H.B.M. Commissioner Alfred Sharpe, C.B., at Zomba, British Central Africa, which was stated to be probably the largest species of Coccid yet discovered, the maximum measurements being 20·50 mm. long and 10 mm. high. As in the genus *Callipappus* the abdomen was intus-suscepted, forming a pouch for the reception of the ova and the hatching of the larvæ. 6258 of the latter were taken from the body of a single female.

EDINBURGH.

Royal Society, November 19.—Prof. Copeland, Vice-President, in the chair.—The chairman gave the substance of communications from the Scottish Office, Whitehall, and from the Nobel Committee of the Royal Swedish Academy of Sciences, as to the Nobel Foundation.—In a paper on the diurnal range of temperature in the Mediterranean during the summer months, Dr. Buchan gave some important conclusions based on the observations made by the staff of the Austrian ship *Pola*. These had been taken at various depths, and a study of them showed that in water deeper than 100 fathoms a daily change of temperature could be detected to a depth of about 150 feet. Thus averaging from 50 distinct sets of observations, he found that the temperature of the surface waters in the afternoon was greater than the temperature in the morning by 1·5° F., and that this difference gradually diminished with increase of depth, having for example the value 0·3° F. at a depth of 100 feet. That such a depth should be reached by the solar radiation seemed very remarkable, and the process by which the heat was lost during the night seemed to demand a careful consideration of our theories of radiation.—Dr. Alexander Bruce read an elaborate paper on the topography of the gray matter and motor cell in the spinal cord, the results being demonstrated by a series of finely prepared lantern slides.

PARIS.

Academy of Sciences, December 3.—M. Maurice Lévy in the chair.—Study of the carbide of samarium, by M. Henri Moissan. A mixture of samarium oxide and carbon, submitted to the temperature of the electric furnace, gives easily a crystallised carbide of the formula SaC_2, comparable with the oxides of lanthanum, cerium, neodymium and praseodymium. This carbide decomposes cold water in a similar manner to the carbides of the alkaline earths, giving a complex mixture of hydrocarbons, rich in acetylene. In this respect samarium behaves more like the ytrrium group and differs from the cerium group of rare earths.—Observations of the comet, 1900 *b* (Borrelly-Brooks) made with the large equatorial of the observatory of Bordeaux, by MM. G. Rayet and A. Feraud. The positions of this comet were measured on nine evenings between September 13 and October 25. On the latter date the comet had still a very faint tail, and the nucleus was slightly elongated.—The changes of solar temperature and the variations of rain in regions surrounding the Indian Ocean, by Sir Norman Lockyer and Dr. W. J. S. Lockyer. A connection is traced between the occurrence of dry and wet seasons and the maximum and minimum temperatures of the sun, as determined by the area of sun spots.—New comparative researches on the products of combustion of different apparatus for lighting, by M. N. Gréhant. The products of combustion from incandescent burners, candles and petroleum lamps were compared, with especial reference to the amount of carbon monoxide produced. The results are best compared by examining the ratio of the volumes of $CO : CO_2$ produced. This ratio was 1 : 655 for the Auer burners, 1 : 1025 for the oil lamps and 1 to 1610 for the candles.—On isothermal surfaces, by M. A. Thybout.—On the minimum of certain integrals, by M. H. Lebesgue.—Geometrography in space, by M. Émile Lemoine.—On the theory of electrocapillary phenomena, by M. Gouy. The author states that the view generally held as to the causes of electrocapillary phenomena, the Helmholtz hypothesis of double layers, is not in accord with experiment. The view is here put forward that forces exist between the mercury and the ions or molecules of the dissolved body which are non-electrical. This leads to the conclusion that there exists in general a triple electric layer, which may, in certain cases, be reduced to a double layer.—Acidimetry of the aldehydes and ketones, by MM. A. Astruc and H. Murco. The behaviour of a large number of fatty and aromatic aldehydes and ketones towards helianthine A, phenolphthalein, and Porrier's blue has been studied. The results are in general accord with the thermochemical data.—On some reactions of substituted anilines, by M. Œchsner de Coninck. An account of the reactions between methyl-, dimethyl-, ethyl-, and diethyl-aniline and copper sulphate, chloride, and acetate, and nickel and cobalt chlorides.—On the presence of an iron thiocarbonate in the water of the Rhone, by M. H. Causse. At certain times of the year the Rhone water possesses the property of restoring the colour to Schiff's reagent. After proving that no aldehyde was present in the water, the reaction was proved to be caused by a thiocarbonate of iron, $FeCO_2S$, which was made synthetically in two or three ways. There appears to be some connection between the amount of this substance present in the Rhone water and the number of cases of typhoid fever in the Rhone valley.—Determination of over-heating or under-heating of plaster of Paris in furnaces, by M. L. Périn.—Permeability of the external wall of the marine invertebrate, not only to water but also to salts, by M. R. Quinton. It is shown experimentally in a decisive manner that the external wall of the marine invertebrate is permeable, not only to water, but to such salts as sodium chloride and phosphate. Hence the higher marine invertebrate, although closed anatomically, is osmotically open, and hence resembles the lower marine invertebrate, physiologically and anatomically, in being a colony of marine cells.—A volatile poison, the cutaneous secretion of *Iulus terrestris*, by M. C. Phisalix. During a research on the action of this venom upon guinea-pigs, it was found that the poison was volatile; hence it is probable that the active principle is not an albumenoid material.—The large migratory Acridians of the Old and New World of the genus Schistocera; their changes in colour according to age and season; the physiological *rôle* of pigments; by M. J. Künckel d'Herculais.—On the disease of the carnation produced by *Fusarium Dianthi*, by M. G. Delacroix. The conidia of *Fusarium Dianthi* can be killed in seven hours by the vapour of carbon bisulphide. Ordinary formalin of commerce, diluted with one thousand parts of water, kills the chlamydospores in an hour.—On the simultaneous production of two nitrogen compounds in the crater of Vesuvius, by M. R. V. Matteucci. During the recent eruption, the simultaneous ejection of rocks covered with sal ammoniac and iron nitride was noticed, and these are regarded as being intimately related in their formation.—Remarks by M. Armand Gautier on the preceding paper.—On the tectonic continuity of Tonkin with China, by M. A. Leclère.—Chemical and mineralogical examination of the Lançon meteorite, by M. Stanislas Meunier.—On some therapeutic applications of light, by M. P. Garnault. Light may be utilised with great advantage in a certain number of diseases, and the results obtained are certainly due to its specific action. The cases most successfully treated are muscular and chronic articular rheumatism, various ulcers and chronic catarrh of the nose and ear.

NEW SOUTH WALES.

Royal Society, October 3.—The President, Prof. Liversidge, F.R.S., in the chair.—Marriage and descent among the Australian aborigines, by R. H. Mathews.—On the constituent of peppermint odour occurring in many Eucalyptus oils, part i., by Henry G. Smith. The first Eucalyptus oil was distilled by Dr. White in 1788, at Sydney, and owing to the great resemblance between this oil and that obtained from the peppermint *Mentha piperita*, he named the tree from which he had obtained the oil the "Peppermint Tree." Its botanical name is *Eucalyptus piperita*. Since then many other species of Eucalyptus have been found to have this peppermint odour, and are generally known as "peppermints." The constituent giving this odour has now been isolated. It occurs in greatest amount in the oil obtained from the leaves of *E. dives*, next in that of *E. radiata*, and in fair amount in the oils of several other species.—On the crystalline structure of gold nuggets from Klondyke, Victoria and New Zealand, by Prof. Liversidge, F.R.S. Sections of three nuggets from Klondyke were shown. The crystal faces are comparatively small, and the nuggets have a granular structure, as if built up of separate grains, of one or two millimetres in diameter. They are also more fissured and contain more cavities than usual. The sections of Victorian (Australian) and New Zealand nuggets are also made up of small crystals, and they present numerous small cavities after the removal of the quartz and iron oxide by treatment with hydrofluoric and hydrochloric acids, so that the sections present quite a different appearance to the very compact and largely crystallised nuggets from West Australia.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 13.

ROYAL SOCIETY, at 4.30.—On the Spectrum of the More Volatile Gases of Atmospheric Air, which are not Condensed at the Temperature of Liquid Hydrogen. Preliminary Notice: Prof. Liveing, F.R.S., and Prof. Dewar, F.R.S.—Additional Notes on Boulders and other Rock Specimens from the Newlands Diamond Mines, Griqualand West: Prof. Bonney, F.R.S.—The Distribution of Vertebrate Animals in India, Ceylon and Burma: Dr. W. T. Blanford, F.R.S.—Elastic Solids at Rest or in Motion in a Liquid: Dr. Chree, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—The Syzygetic Theory of Orthogonal Bivariants: Prof. Elliott, F.R.S.—On Discriminants and Envelopes of Surfaces: R. W. Hudson.—Note on the Inflexions of Curves with Double Points: H. W. Richmond.—On some Properties of Groups of Odd Order, ii.: Prof. Burnside, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Possible continuation of Discussion on Mr. Langdon's paper.——*Time permitting*: Rapid Variations in the Current through the Direct Current Arc: W. Duddell.

CHEMICAL SOCIETY, at 8.30.—Rammelsberg Memorial Lecture: Prof. H. A. Miers, F.R.S.

FRIDAY, DECEMBER 14.

PHYSICAL SOCIETY (Royal College of Science), at 5.—(1) Electric Inertia; (2) The Effect of Inertia on Electric Currents in a Rotating sphere: Prof. A. Schuster, F.R.S.—Exhibition and Description of a Quartz-Thread Gravity-Balance: Prof. R. Threlfall, F.R.S.—On the Theory of Magnetic Disturbances by Earth Currents: Prof. A. W. Rücker, F.R.S. Notes on the Practical Application of the Theory of Magnetic Disturbances by Earth Currents: Dr. R. T. Glazebrook, F.R.S.—The New Physical Laboratories of the Royal College of Science: Prof. A. W. Rücker, F.R.S.—Exhibition of a Set of Half-Seconds Pendulums: W. Watson.

ROYAL ASTRONOMICAL SOCIETY, at 8.—On the Connection between Solar Spots and Earth-Magnetic Storms: Rev. W. Sidgreaves.—Watch for the Leonids, 1900, at Markree: F. W. Henkel.—The Diameter of Juno (3), determined with the Micrometer of the 40-inch Refractor of the Yerkes Observatory; with Remarks on some of the other Asteroids: E. E. Barnard.—Observations of the Leonids made at Blackheath, 1900 November 14: E. M. Antoniadi and A. C. D. Crommelin.—The Leonids: Observations at the University Observatory, Oxford: H. H. Turner.—Ephemeris for Physical Observations of Jupiter, 1901: A. C. D. Crommelin.—The System of ζ Herculis: T. Lewis.——*Probable paper*: Observations of Capella as a Double Star with the 28-inch Equatorial of the Royal Observatory, Greenwich; W. H. M. Christie.

MALACOLOGICAL SOCIETY, at 8.—Note on *Bensonia* and an apparently undescribed Species, *B. mimela*: W. T. Blanford.—Note on *Bensonia mainwaringi* and *Macrochlamys dalingensis*: W. T. Blanford.—Further Notes on the British Pliocene Non-Marine Mollusca: A. S. Kennard and B. B. Woodward.—The Anatomy of *Beddomea* and the Relationships of *Amphidromus*: Henry A. Pilsbry.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—Power-Gas and Large Gas-Engines for Central Stations: H. A. Humphrey.

SATURDAY, DECEMBER 15.

ESSEX FIELD CLUB (Essex Museum of Natural History, Stratford), at 6.30.—Notes on the Mollusc *Paludestrina jenkensi*, Smith, in Essex and elsewhere: A. S. Kennard and B. B. Woodward.—Aquatic Autocrats and Fairies (Lecture): Fred. Enock.

MONDAY, DECEMBER 17.

SOCIETY OF ARTS, at 8.—Electric Oscillations and Electric Waves: Prof. J. A. Fleming, F.R.S.

TUESDAY, DECEMBER 18.

ZOOLOGICAL SOCIETY, at 8.30.—Notes on the Fauna of the White Nile and its Tributaries: Captain Stanley S. Flower.—An Account of a Large Branchiate Polynoid from New Zealand (*Lepidonotus giganteus*, Kirk): W. Malcolm Thomson.—On a New Genus of Flat-fishes from New Zealand: H. M. Kyle.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Papers to be further discussed*: The Signalling on the Waterloo and City Railway; and Note on the Signalling of Outlying Siding Connections: A. W. Szlumper.—Signalling on the Liverpool Overhead Railway: S. B. Cottrell.——*Papers to be read, time permitting*: Glasgow Bridge: B. Hall Blyth.—Railway Bridge over the Fitzroy River, at Rockhampton, Queensland: W. J. Doak.—The Niagara Falls and Clifton Steel Arch Bridge: L. L. Buck.

ROYAL STATISTICAL SOCIETY, at 5.—The Statistical Results of the State Monopoly of Spirits, established in Russia in 1895, and its Influence on the Economic Development and Morality of the Population: Alexis Raffalovich.

ROYAL PHOTOGRAPHIC SOCIETY, at 8.—Photography in War: H. C. Shelley.

WEDNESDAY, DECEMBER 19.

GEOLOGICAL SOCIETY, at 8.—On the Igneous Rocks associated with the Cambrian Beds of the Malvern Hills: Prof. T. T. Groom.—On the Upper Greensand and Chloritic Marl of Mere and Maiden Bradley in Wiltshire: A. J. Jukes-Browne and John Scanes.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—The Seasonal Rainfall of the British Isles: Henry Mellish.—A Review of Past Severe Winters in England, with Deductions therefrom: Albert E. Watson.

ROYAL MICROSCOPICAL SOCIETY, at 8.—A Demonstration of Lantern Projection in Conjunction with the Microscope: Mr. Barton.

THURSDAY, DECEMBER 20.

LINNEAN SOCIETY, at 8.—On the Structure and Habits of the *Ammocharidas*: Arnold T. Watson.—The Flora of Vavau, one of the Tonga Islandx: J. H. Burkill.—Warning Colours in Insects: Prof. E. B. Poulton, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Lecture on the Electrical Engineers (R.E.) in South Africa: Lieut.-Colonel Crompton.

CHEMICAL SOCIETY, at 8.—On the Union of Hydrogen and Chlorine: J. W. Mellor.

FRIDAY, DECEMBER 21.

INSTITUTION OF CIVIL ENGINEERS, at 8.—The Use of Geometrical Methods in investigating Mechanical Problems: C. E. Inglis.

A MODERN SCIENTIFIC INDUSTRY.

Jena Glass and its Applications to Science and Art. By Dr. H. Hovestadt. Pp. xii + 429. (Jena: Fischer, 1900.)

THIS is a volume of some four hundred pages, in which Dr. Hovestadt has collected a mass of information about the Jena glass.

In a report on the scientific apparatus of the London Exhibition of 1876, Abbe called attention to the need for progress in the art of glass making if the microscope were to advance, and to the necessity for obtaining glasses having a different relation between dispersion and mean refractive index than that found in the material then at the disposal of opticians.

He referred to the attempts made in England by Harcourt and Stokes with this object, and to the causes of their failure.

The task thus indicated was undertaken in 1881 by Abbe himself and Schott at Jena. The first catalogue of the Jena Laboratory, published in 1886, contains these words: "The industrial undertaking which is here announced for the first time arose out of a scientific investigation into the connection between the optical properties of amorphous fluxes and their chemical constitution."

The experimental work was only rendered possible by repeated and large subventions from the State. The immediate consequence of the undertaking was that by 1888 nearly all the glass required for optical work in Germany was of home manufacture; in a few years more an export trade in the raw glass began, the value of which in 1898 was over 30,000*l.*, while the value of the optical instruments, such as telescopes, spectacles, field glasses and the like, exported in the same year was nearly 250,000*l.* The trade at present employs some 5000 workmen.

When Abbe and Schott began their work, some six elements only entered into the composition of glasses. By 1888 it had been found possible to combine with these six quantities, up to at least 10 per cent., of twenty-eight additional elements, and the effect of each of these on the refractive index and dispersion had been determined.

Thus, for example, these investigators had found that by the addition of boron the ratio of the length of the blue end of the spectrum to that of the red is reduced; while fluorine, potassium and sodium produce opposite results.

Now an ordinary achromatic lens, uniting two colours of the spectrum, is formed by combining a crown glass lens with one of flint glass having equal total dispersion; but though the total dispersion is the same for the two it is differently distributed throughout the spectrum. In the flint glass the dispersion of the blue end is greater, that of the red less, than in the crown; hence the light from a white source is not white after traversing the lens; a "secondary" spectrum remains, and it was the existence of this which rendered the progress of the microscope so difficult. Abbe's experiments showed how the difficulty was to be met. By combining a high proportion of boron with flint glass, its spectrum became more nearly the same as that of a crown glass. Such a glass had been made by Harcourt many years previously, while a glass containing phosphates instead of silicates is found to have the same dispersion as, combined with a higher refractive index than, the ordinary crown glasses, and therefore serves better to achromatise the borate-flint glass. In fact, Abbe showed that with two such glasses it is possible to combine three colours instead of only two; the outstanding spectrum is greatly reduced in length, and is called a "tertiary" instead of a "secondary" spectrum.

Again, the ordinary microscope lens of two glasses can be corrected for axial spherical aberration for one colour only. Abbe showed that the new borate-phosphate lenses could, by combination with a lens of fluor-spar, have their axial spherical aberration corrected for two colours. These lenses he called apochromatic.

It was found more difficult to reduce the secondary spectrum by lengthening the red end of the spectrum of the crown glass. This required the addition, as we have said, of fluorine, potassium or sodium. The effect of sodium is small; glasses with a large amount of potassium can be made, but are very hygroscopic, while the introduction of fluorine though it was successfully effected, is involved with many difficulties.

The book under review gives, in its first two chapters, an account of the preliminary work of Abbe and Schott, and full details as to the optical properties of the glasses now made. The next four chapters deal with the optical instruments manufactured out of the glasses.

We have already referred to the fundamental improvement in the microscope rendered possible by their use; the problem to be solved in the case of a photograph lens was somewhat different. It follows, from the work of von Seidel, that, with the ordinary crown and flint glasses, the conditions for achromatism and for flatness of field cannot be satisfied together. To do this it is necessary to find a glass of high refractive index and low dispersive power, or *vice versâ*. In ordinary glasses refractive index and dispersive power go together.

Thus, ordinary hard crown glass has a refractive index of 1·518 and a dispersive power of ·0166, while for extra dense flint the figures are 1·717 and ·0339. An achromatic lens might be constructed out of these two glasses, but the field could not be flat.

By introducing barium, however, into the crown glass, a change is produced in this respect. Thus for barium silicate crown the refractive index and dispersive power are 1·573 and ·0173, while for soft crown they are 1·515 and ·0177. With these two glasses, the problem of constructing a photographic object-glass possessing achromatism and flatness of field becomes possible. For the various methods of solution we must refer to the book[1] itself, in which also will be found details as to the use of the glasses for telescopic lenses.

The mechanical properties of glass are next considered, and in Chapter ix. we come to a careful discussion of the imperfect elasticity of glass, specially in connection with thermometry.

[1] See also "Contributions to Photographic Optics," by Dr. Otto Lummer, translated by Prof. S. P. Thompson.

"About twenty years ago" (the quotation is from the catalogue of the German Instrument Exhibition at Paris) "the manufacture of thermometers had come to a dead stop in Germany, thermometers being then invested with a defect, the liability to periodic changes, which seriously endangered German manufacture. Comprehensive investigations were then carried on by the Normal Aichungs-Kommission, the Imperial Physical and Technical Institute, and the Jena Glass Works, and much labour brought the desired reward."

Dr. Hovestadt's account of the labour is most interesting and instructive.

The ice point of a newly made mercury thermometer is known to rise as the thermometer gets older; this rate of rise decreases with the time, finally becoming very slow. If, however, the thermometer be heated to, say, 100° C., and its ice point be taken very shortly afterwards, the reading will be below that observed prior to the observation of the steam point. This depression of the zero varies in amount in different thermometers. It was found (Weber in 1883 and Wiebe 1885–1886) to be specially large in the case of thermometers made of Thuringian glass, amounting in the case of one thermometer examined to 0°·65. As a consequence, the readings of the thermometers were quite uncertain, depending greatly on the past history of the instrument employed. It was this defect which Schott and Abbe set out to cure. Weber had observed that glasses which contained a mixture of potash and soda gave a very large depression. He succeeded in 1883 in making a glass entirely free from soda, in which the depression was only about 0°·1. The work was then taken up by the Aichungs Commission and the Jena factory. A number of thermometers of varying age and manufacture were examined as to the depression, and the glass of these thermometers was then analysed. Weber's conclusions were abundantly verified. An old thermometer of Humboldt's, containing 0·86 per cent. of Na_2O and 20·09 per cent. of K_2O, had a depression of 0°·06; a new instrument, in which the percentages of the two substances respectively were 12·72 and 10·57, had a depression of 0°·65. It is possible that this last thermometer was too new to give quite trustworthy results, but the difference is very marked. An English standard thermometer, with 1·54 per cent. of Na_2O and 12·26 per cent. of K_2O, had a depression of 0°·15, while a French "verre dur" thermometer, with 12·02 of Na_2O and 0·56 of K_2O, showed a depression of only 0°·008.

The next step was to manufacture a German glass with a low depression. The now well-known normal thermometer glass distinguished by the mark 16‴ was the outcome of the experiments. This is a pure soda glass having the following composition:—

SiO_2, 67·5%; Na_2O, 14%; CaO, 7%; Al_2O_3, 2·5%; ZnO, 7%; B_2O_3, 2%,

and the depression observed is 0°·05.

The hydrogen thermometer is, however, the ultimate standard of appeal in thermometry, and it was necessary, therefore, to compare the new instruments with such a thermometer.

Details of the work are given in the book. It appeared, from the results of Wiebe and others, that at a temperature of 40° there was a difference of 0°·12 between the two nstruments. Experiments showed, however, that it was possible to produce a glass agreeing more closely with the gas thermometer than this, and this fact led to further work and to the manufacture of the boro-silicate glass 59‴ with the following analysis:—

SiO_3 72%; Na_2O, 11%; Al_2O_3, 5%; B_2O_3, 12%.

This was found to show a smaller ice point depression, amounting, according to Hovestadt, to 0°·02, and to agree more closely over the range 0° to 100° with the hydrogen thermometer, the difference being greatest at 30°, where it amounts to 0°·038. For temperatures above 100° the differences are considerably greater than those given above, and the agreement between the scales is better for 16‴ than for 59‴.

For details, however, of these comparisons, and of much more work of great interest as to the properties of these special glasses, reference must be had to the book. It constitutes a great record of what is to be achieved by the application of science, that is, "organised common sense" to an important industry. In England we have done nothing to compare with it. As a consequence, Germany can claim that "the manufacture of thermometers has reached in Germany an unprecedented level, and now governs the markets of the world." Such are the results obtained in twenty years by Abbe and his colleagues.

R. T. G.

ESSAYS BY DR. WALLACE.

Studies, Scientific and Social. By Alfred Russel Wallace. 2 vols. Illustrated. (London: Macmillan and Co., Ltd., 1900.) Price 18*s.*

IN addition to being one of the originators of the modern doctrine of animal evolution and one of the leading pioneers in the study of the geographical distribution of the earth's fauna, Dr. Russel Wallace is a writer noted for such a fascinating style and such a happy mode of presenting his views, that any work from his pen is sure of a hearty reception on the part of the more thoughtful section of the reading public. And even those who by no means agree with all his views—whether on scientific or social questions—cannot fail to admire the fairness with which he treats debatable points, and the temperate manner in which he replies to and discusses the objections raised by his critics.

The essays and articles collected in the two volumes before us embrace an extraordinarily wide range of subjects, and cover a period of no less than thirty-five years, the earliest of them being published as long ago as 1865, while the latest saw the light as recently as 1899. The variety of subjects discussed is alone a testimony to the wonderful mental capacity of their talented author, while the number of the periodical publications from which they have been culled bears evidence to the popularity of his writings. Those embraced in the first volume relate exclusively to various branches of geological and biological science, while those in the second are devoted to educational, political, sociological and kindred subjects. With the exception of a brief reference to two articles in the second volume dealing with museums as educational

establishments, our notice will be restricted to the section connected with natural science.

It may be as well to mention, before going further, that in a work dealing with such a variety of subjects as is the case with the one before us, it would be a practical impossibility to review it critically within any reasonable space; and we must accordingly content ourself with a brief survey of its principal contents.

Quite apart from the general interest of the book, as dealing with some of the most important biological and social topics of the day, there can be no question that, from the point of view of the working naturalist, the author has been well advised in publishing the essays of which it is composed in a collective form. Several of them are replies to criticisms on some of Dr. Wallace's views, while others, such as the one on the affinities and origin of the Australian and Polynesian races, contain entirely new views and theories. Before their publication in their present form it was, consequently, exceedingly difficult for a writer on any particular zoological subject to be sure that he had seen Dr. Wallace's last words on that subject. Indeed, the writer of this notice feels that he owes an apology in that, when writing an essay in favour of the Caucasian affinities of the Australians, he was unaware that Dr. Wallace had previously urged the same view. In one respect, the omission may perhaps be regarded as fortunate, as it permitted the same conclusion to be reached independently.

From the fact that some of the articles are more or less recent while others are of considerable antiquity, it will, of course, be evident that they have by no means all an equally important bearing on disputed questions of the day. The one on the evolution and distribution of animals, for example, dates from the early days of the study of that subject, whereas that on the distinction between the Palæarctic and Nearctic regions deals with a proposed amendment of the author's classification.

The first five essays deal mainly with the agencies that have modified certain parts of the surface of the globe, the alternations that have taken place in the distribution of sea and land, and the state of the interior of the globe. In the main, Dr. Wallace is a strict uniformitarian, and his account of how even the deepest and steepest mountain valleys have been eroded by the ordinary denuding agencies will be read with interest. He is fully convinced of the important part played by ice in the modelling of the earth's surface during the Pleistocene period, and pays no heed to the arguments that have been urged of late years against the former existence of an ice age. Whether his adherence to the theory of the erosive action of ice as the dominant factor in the formation of lake-basins will commend itself to many modern geologists may be doubtful; and the denial by some that such a thing as a true rock-basin exists would, if fully confirmed, to a great extent annul several of his arguments.

In the essay on the permanency of ocean-basins the author, in the main, pleads in favour of his original views, and offers some objections to the theory of large continental and ocean changes which demand respectful and serious attention on the part of those who differ from him in this respect. Nevertheless, in granting the possibility that such alternations of sea and land may have extended to such parts of the ocean as lie approximately within the limits of the two thousand fathom line, he has conceded much that is demanded by his opponents. Indeed this extension of the limits (formerly fixed at the 1000 fathom line) would practically admit of a land connection, at least by way of Antarctica, between South America and Africa, if not also between South America and Australia. And to learn how strong is the evidence in favour of such connections, the reader need only consult the paper recently read by Prof. Scott before the British Association.

Among the essays on descriptive zoology, attention may be confined to the one on monkeys and their affinities, which originally appeared (without the illustrations) in the *Contemporary Review* for 1881. It is an interesting and well written survey of the leading groups of these animals, in the course of which the author raises the question whether the Primates, other than man, are rightly regarded as the head of the animal kingdom. In this article, as in several others, we think it a pity that the author has not seen fit to adapt his nomenclature to that now current among systematic zoologists, and that he clings to such discarded names as Cynocephalus, Mycetes and Cuscus. Moreover, we notice on page 156 the misprint *babuino* for *babuin*; and we venture to affirm that the statement on the following page to the effect that the mandrill in size and strength is not much inferior to the gorilla is scarcely consonant with the facts—certainly not so far as size alone is concerned.

Of the articles on geographical distribution, two deal with North American flowers and trees and their differences from those of Europe, a third treats of the beetles of Madeira and the inferences to be drawn from them, while to the other two a brief reference has been already made.

Five essays are devoted to the theory of evolution, among which special attention may be directed to the one dealing with the question of the possibility of acquired characters being inherited, which appeared in the *Fortnightly Review* for 1893. At the conclusion of this article Dr. Wallace remarks "that no case has yet been made out for the inheritance of individually acquired characters, and that variation and natural selection are fully adequate to account for those various modifications of organisms which have been supposed to be beyond their power."

To many readers the three essays on anthropological subjects will perhaps prove the most interesting in the whole book. The first of these deals with the Polynesians and their migrations, the second gives an account of New Guinea and its inhabitants, and the third treats of the affinities and origin of both Polynesians and Australians. In the title of the second member of this trilogy the author has scarcely done himself justice, since, in addition to describing the Papuans, he gives a most interesting summary of the leading features of the mammalian and avian fauna of the largest island in the globe. The illustrations of some of the recently discovered types of birds of paradise in this article are among the most exquisite examples of photogravure that have come under our notice. Well selected, too, are the anthropological photographs with which these articles are illustrated, and especial attention may be directed to the juxtaposed portraits of an Australian

and a Yeso Ainu, which the author considers afford important evidence in favour of the Caucasian affinities of the former race. Mr. Wallace, in opposition to the views of the late Sir William Flower, likewise advocates a Caucasian descent for the brown Polynesians. The use of the bow and arrow by the Papuans, and not by either the Australians or the Polynesians, is, he remarks, a notable ethnical fact. It clearly, indeed, serves to differentiate the Australians from the Papuans and other Melanesians; but then, on the other hand, it might also be used as an argument that the Polynesians are related to the Malays, who likewise never use the weapon in question. It may be remarked as somewhat strange that, when the author alludes to the possession of the boomerang by races other than the Australians, he omits to mention its use by certain Indian jungle tribes.

With one article on the problem of instinct, and a second on human selection, the latter worthy the best attention of those interested in the well being and improvement (both physically and morally) of the human race, the first of these two most interesting volumes is brought to close.

In the second volume our remarks, as already said, will be restricted to the first two articles, one of which deals with how an ideal zoological museum should be constructed and arranged in the best manner for educating the public, while the second discusses how near an approach to this ideal is made by the museums of the United States. The author seems to be clearly of opinion that a most important, if not, indeed, the prime function of a museum should be as an educating medium. In his main ideas he is in accord with the opinions of the late Sir William Flower, and he points out that a perfect museum ought to embrace everything from the lowest worm to the highest product of human art and skill. He also advocates the exhibition of a comparatively limited number of specimens (which should be the best that money can obtain), in order not to confuse by multitude, and also that these should have ample space. The allotment of separate chambers to particular groups is likewise made a point, because, as he urges, a long gallery only serves to distract the attention of the visitor from the objects immediately before him to those ahead, and thus inevitably leads to hurry and an imperfect study. Lastly, but not least in importance, Dr. Wallace advocates the arrangement of zoological collections according to local faunas, instead of according to the affinities of the animals themselves.

Whether or no this faunistic arrangement should be adopted for the main exhibited series in a museum may be an open question; but there can be no question at all that such an arrangement should be displayed in every national museum. The American Museum of Natural History shows in one case the animals living within a fifty-mile radius of New York, and in a second the characteristic members of the European fauna; and nothing of this nature can be of higher educational value. With regard to limiting the number of specimens exhibited, a difficulty occurs, since a museum—at any rate in England—has at least two distinct classes of visitors for whom to cater. For the ordinary lover of natural history, as well as for the general zoological student, to say nothing of "the man in the street," a small number of specific representatives of various groups is not only sufficient, but forms the best kind of exhibit he can be shown. On the other hand, although the working zoologist will find what he requires in the study series, the sportsman—and in Britain his name is legion—expects to find exhibited every species and race of furred and feathered game he may encounter in the course of his wanderings. To find a *via media* out of this difficulty is a problem which will probably long continue to vex the mind of the museum curator; but, like other difficulties, it will one day have to be faced and conquered.

Our best wish to the many readers whom Dr. Wallace's two volumes will undoubtedly attract is that they may derive from their perusal an amount of interest and instruction equal to that which has accrued to the present reviewer in the accomplishment of his task.

R. L.

BRITISH BRAMBLES.

Handbook of British Rubi. By William Moyle Rogers, F.L.S. Pp. xiv + 111. (London: Duckworth and Co., 1900).

MR. ROGERS' "Handbook of British Rubi" is not a work likely to excite a wide interest. As the offering to his fellow "batologists" of "a diligent student of British brambles for nearly a quarter of a century," it appeals to a restricted circle. No general worker in the field of systematic botany can hope to master the fine distinctions which discriminate the great majority of the so-called species; in fact, the general systematist will see at once that the batologist and he are widely at variance as to the limitation of species, and that for purposes of comparison with those of other genera and of a comparative study of floras the 'species' of British Rubi are useless. Generally speaking a 'species' is to some extent a personal matter, sometimes varying considerably in different conditions of one and the same person; but the entities recognised by several workers in one group usually bear an appreciable relation to each other and to those of other groups. It is not too much to say that there is no comparison whatever between the species of the batologist and the species of the botanist.

In Sir Joseph Hooker's "Student's Flora," which we may regard as the expression of the views on the British flora of our greatest living systematist, four species of *Rubus* are recognised, namely, *R. Chamaemorus* (the cloudberry), *R. saxatilis*, a small low-growing, sub-alpine plant rare in the south and east of England; *R. Idaeus* (the raspberry), and *R. fruticosus* (the blackberry or bramble); under the last-named twenty-two forms or subspecies are enumerated. Bentham, in his "Handbook of the British Flora," has five species, *R. caesius* (the dewberry) ranking as a species, whereas in the Student's Flora it is regarded as a subspecies of *R. fruticosus*. Babington, whose manual is generally recognised as the best critical account of our flora, and who paid some attention to the *Rubi*, makes forty-eight species by raising to specific rank a number of forms of *R. fruticosus*. Mr. Rogers, by a further elaboration of the same species, admits one hundred and three, many of which are subdivided into subspecies or varieties.

Thus *R. anglosaxonicus* has four subspecies and *R. dumetorum* eight varieties, and of the latter Mr. Rogers says,

"Other undescribed forms of this aggregate no doubt exist in Great Britain, and a further study of these may possibly justify the addition of one or more new varieties to the preceding list."

Thirteen of the species and a fair proportion of the varieties and subspecies are peculiar to the British Isles, occurring mainly in very restricted areas. *R. durescens*, for instance, is known only in Mid-Derbyshire, and *R. mercicus* is "at present known with certainty only between Water Orton and Minworth, Warwickshire."

We do not wish to underrate the value of the work of Mr. Rogers and his fellow-batologists, who, moreover, are not wholly responsible for the present state of batology. They are disciples of Dr. W. O. Focke, of Bremen, whose epoch-making visit to England in 1889 is referred to almost as the missionary visit of an apostle. The handbook is a monument of patient toil and critical examination; each species, subspecies and variety is described with a care and fulness which many botanists would do well to emulate; notes on habitat are given, the distribution, if any, on the Continent is recorded, and there are also many remarks of a critical nature on the affinities of the form in question. An appendix contains a list of the botanical counties for which each species is recorded; and the thorny path of the student is somewhat eased by a key to the groups and a brief conspectus of the species which precede the detailed descriptions.

As a study in the variation of a highly variable species, the book is a store of valuable information, which, if carefully collated and arranged, might yield results of great interest, especially if more particulars as to habitat and environment were included. However, Mr. Rogers' aim has been to record and systematise, for the benefit of students of batology, facts already ascertained, and he has carried out his task in a manner which, except for a few details, is beyond criticism, and calls for the gratitude of all batologists present and to come.

A. B. R.

EXPERIMENTAL FRUIT-FARMING.

Report of the Working and Results of the Woburn Experimental Fruit Farm. By the Duke of Bedford and Spencer U. Pickering, F.R.S. Second report. Pp. v + 260. (London: Eyre and Spottiswoode. 1900.)

IN few departments of plant cultivation is empiricism more rampant than in the cultivation of fruit-trees. The methods of pruning and other cultural details have been handed down from our forefathers with little or no attempt to regulate them by scientific methods, whilst, in too many instances, absolute neglect has prevailed and fruit-growing has, in consequence, been deemed unprofitable at the very time when thousands upon thousands of barrels of apples are imported annually from the United States, Canada and Tasmania. In some cases this foreign supply comes in when our own crop is exhausted, but, speaking generally, a very large proportion of the fruit crop might be grown here just as well as in the States were our farmers endowed with the same business capacities as their brethren across the Atlantic. Recognising the importance of these facts, the Duke of Bedford has established near Woburn an experimental fruit-farm, where, under the directions of Mr. Pickering, experiments are being carried out on various cultural methods applied to fruit trees and to bush fruit. At the same time, demonstration plots are planted with a view of showing to the farmers what kinds of apples and other fruit trees may be grown in that particular locality with a reasonable expectation of profit.

The farm has now been established for five years. The first report, published three years ago, was naturally devoted largely to a general account of the ground and of the experiments then commenced. The present volume deals more largely with results. Those who have no leisure to investigate the statistical details will be able to glean a good general idea of their purport from the perusal of the table of contents and the general summary given in the appendix.

The experiments made with a view of destroying the currant-bud mite were very numerous and very unsatisfactory. Although at Wye College the use of hydrocyanic vapor has been found serviceable, it was found of no avail at Woburn. It would seem, however, that our efforts will be negative until we know more of the life-history of the mite. Perhaps the study of the manners and customs of the hazel-bud mite might furnish a useful clue to our knowledge of the nearly allied currant-bud mite.

Eighty-five varieties of strawberries were under observation, but it was not found possible to trace any definite connection between the amount of the crop they furnished and the meteorological phenomena to which the plants were subjected. Moreover, the results of the application of manures, artificial or natural, are stated to be "ambiguous," a fact which points to the inference that the soil is sufficiently fertile without the application of manure.

The results of pruning at various times and of differen methods of performing the operation are tested by weighing a certain number of leaves from the trees, and by measuring the height and girth of the trees. From these experiments, it would seem as if further time is required to estimate the value or otherwise of the different methods of pruning. Root pruning, a practice largely adopted by gardeners to check undue luxuriance and promote fertility, is made the subject of other experiments by Mr. Pickering and his lieutenant, Mr. Castle. Although root pruning acts as a check to vegetation, it generally also results in the formation of a large quantity of fibrous roots and root-hairs, so that the absorbent power of the roots must be increased, and we might have expected the vegetation to be correspondingly enhanced. There is a little inconsistency here which we hope the Woburn experiments may ultimately clear up.

Perhaps the most striking result yet obtained is that showing the injurious effect of growing grass round the fruit trees, the injury being attributed to the increased evaporation from the soil and the consequent exposure of the trees to drought. Many of our orchards are in grass, but as they are "fed off" by sheep the injurious results may, in a measure, be counteracted by the manure so supplied. Other experiments we can not here further allude to, but, in conclusion, we can but emphasise the

great importance of the experiments which are carried out by the munificence and public spirit of the Duke of Bedford. Each year their value and importance will be enhanced. If we might make one suggestion it would be that a corresponding series of experiments, though not necessarily on so large a scale, might be made on barren sand or some soil less naturally fertile than that at Ridgmont. MAXWELL T. MASTERS.

OUR BOOK SHELF.

Design in Nature's Story. By Walter Kidd, M.D., F.Z.S. Pp. ix+165. (London: James Nisbet and Co., Ltd., 1900).

HUXLEY pointed out that the Darwinian theory of adaptations was incompatible with "the commoner and coarser forms of teleology," but admitted that "there is a wider teleology, which is not touched by the doctrine of Evolution." But Dr. Kidd is not satisfied with this, and has written a little book to protest against the attempt of modern science to ignore what is called "Design in Nature." He does not trouble himself to define with any precision what he means by this phrase, but he seems to mean what is called "the directive intelligence of a personal God," and we can only repeat what has been said so often, that with this the scientific mood, as such, has nothing whatever to do, though it supplies some of the data with respect to which the philosophic mood may decide as to the validity and fittest formulation of the conception. When Weismann says, to the author's disgust, that the introduction of teleological principles is the ruin of science, he simply expresses the general conviction that their introduction is incongruous with the scientific method. Dr. Kidd does not seem to see that to oppose scientific and teleological interpretations is to oppose incommensurables.

The author gives examples of adaptations in plants, in animals, and in man, but Darwin's illustrations are far more convincing. He emphasises also "the adaptedness of environments for coming organisms," though it seems plain enough that only those organisms could come to stay who were relatively fit to survive in the given conditions. If the author will reconsider, for instance, the position expressed by W. K. Brooks in his "Foundations of Zoology," he may discover that he is tilting against a windmill, that Darwin did at least as much for teleology as Paley, and that our provisional theories of the rise and progress of adaptations suggest no reason whatever why the philosophers should not adhere to the teleological position. But these discoveries should have been made before publication. J. A. T.

Penrose's Pictorial Annual. Vol. vi., *The Process Year-book for* 1900. Edited by William Gamble. Pp. xvi +112. (London: Penrose and Co., 1900).

THIS handsome volume will give the reader an excellent idea of the way in which photographs *can* be reproduced for illustration purposes. It is too often the case that either copies of photographs have to be made quickly or the paper on which they are printed is not of the most appropriate kind, so that the "reproduction" is by no means of a very high order. In this annual, however, the editor has taken great care that the art of reproduction should be given its full scope, and any reader cannot but admire the results as here displayed. From the beginning to the end of the volume we find innumerable illustrations, dealing with all kinds of subjects and reproduced by nearly as many processes. The illustrations are as nearly perfect as reproductions can be, and show that a sound practical knowledge has been utilised throughout. The editor states that "We have tried to show what photomechanical processes can do at the present time, and to present the specimens of the numerous British and foreign firms in a style which will bring out every quality in the plates." That this has been carried out in a highly satisfactory manner cannot be denied.

Many hints may be gathered from the numerous articles scattered throughout the volume, especially from that written by the editor on catalogue illustrations.

In conclusion it may be stated that every one interested in the subject of process work, and who wishes to know its position to-day, cannot do better than examine closely the examples displayed throughout the pages of this volume, which is a model of good printing and get-up.

Knowledge Diary and Scientific Handbook for 1901. (London: *Knowledge* Office, 1900.)

THIS publication is one which appeals more particularly to those interested in astronomy, and will doubtless prove a great convenience to actual observers for recording their observations, and to others for use as a private diary. There is a generous allowance of space for each day, and provision is made for recording correspondence. In addition, there are 120 pages of printed matter, consisting of the principal astronomical data for the year, a calendar of notable events, a variety of useful tables, and reprints of a few articles of more than passing interest which have appeared in *Knowledge.* Star maps, showing the aspect of the heavens for each month, are also given. As the recognition of the planets is apt to be a source of difficulty to beginners, it would be well in future issues to state the times of their rising and setting as well as of their southing, and to indicate their places month by month in connection with the star maps.

A Short Course of Elementary Plane Trigonometry. By Charles Pendlebury. Pp. xi+160. (London: George Bell and Sons, 1900.)

THIS short course is intended for those who do not require more than a very elementary knowledge of the subject. The treatment adopted is therefore very simple and the language plain. The book is divided into four parts. The first includes definitions, trigonometrical ratios, and multiple and sub-multiple angles, &c.; the second contains a short account of the use of logarithms and mathematical tables. In the third part the solution of triangles, determination of areas of triangles, and the treatment of circles and other figures associated with a triangle are dealt with. Part iv. contains the solutions of some of the more simple trigonometrical equations and also numerous questions on bookwork and answers to the many examples given in the book. As a first course for beginners the book should prove useful.

Lehrbuch der anorganischen Chemie. Von Prof. Dr. H. Erdmann. Zweite Auflage. Pp. xxvi+757. (Brunswick: Viewig und Sohn, 1900.)

THE first edition of this book, published two years ago, was noticed in these columns at some length. The present edition does not materially differ from it, but numerous additions of detail have been made in order to bring the book up to date. Conspicuous among these additions is information about the new gases—here called Edelgase, presumably from their relegation to Mendeleef's seventh group. A fine chromo-lithograph of the spectra of the gases has been added. If there is a want of connectedness and philosophy in Prof. Erdmann's book, there is certainly an abundance of interesting detail collected from a wide field, and on this must lie its chief claim to recommendation.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Chemical Products and Appliances at the Paris International Exhibition.

I SEE that attention has been called in these columns to the excellence of the German catalogue of instruments of precision distributed at the recent Exhibition. It will be of interest if, as a member of the jury representing Great Britain for Class 87, I may be permitted to add that the German catalogue explanatory of the collective chemical exhibits of that country is also a remarkable production, worthy of a permanent place on our library shelves. Copies of this work, printed and got up in a highly artistic way with German text, were distributed among the members of the jury by my friend, Geh. Rath. Dr. Otto N. Witt, the titular member representing Germany on our jury. A French edition was afterwards to be had on application to the custodian of the German exhibits. The work consists of over 200 pages, each embellished with a coloured floral design as a heading, and contains a general introduction, giving an account of the development of German chemical industry, the value of the production in this branch of manufacture for the year 1897 being estimated at 47,395,132*l.* (947,902,645 marks). The introductory part, which is from the pen of Dr. Witt, is followed by a special part containing the history, an account of the nature of the products manufactured, the equipment of the factory and scale of production, and a list of the exhibits of each of the ninety firms represented in the collective exhibit. Those who visited the Exhibition and made an examination of the chemical exhibits of the various countries will have formed their own conclusions as to their respective positions in the scale of chemical industry. At any rate, it is not the object of this letter to institute invidious comparisons—I merely wish to point out that it is not only in instruments of precision that the German catalogue reveals the industrial eminence of that country.

R. MELDOLA.

Electricities of Stripping and of Cleavage.

IN the ordinary process of giving a glazed surface to photographic paper prints by leaving them to dry face downwards upon clean glass, enough electricity is, I find, developed at the moment of separation between the dry glazed print and its glass support to produce a pretty bright illumination in the dark. "Solio" and other gelatino-chloride printing papers being very liable to adhere obstinately to a glass plate in this process, I have only constantly employed it with albumenised printing paper, and have then often noticed strong electrical attraction between the glass plate and the freshly separated paper. Not all glass plates, but apparently only very hard unhygroscopic ones, with a low percentage of soda in their composition, serve the purpose well; and even on these the print must not be freed from superfluous water by any pressure, but by swinging the plate until the water is sufficiently expelled to leave the glass and paper adhering firmly to each other. The paper can be then further freed from water by wiping it on the back, very lightly, with a soft cloth, and any intrusive air-bubbles seen through the glass can be driven out by stroking the back of the print very lightly with the finger. Left then to dry quite horizontally with the paper upwards, the latter will in hot, dry weather or in a very dry, warm room separate itself at last more or less completely from the glass; but in ordinarily damp atmosphere, and cold weather, remains, though sensibly quite dry, adhering to it. The slightest warmth of sunshine or of a fire or gas flame applied to the plate is then enough to make the paper crisp, and leave the glass. This it does with audible clicks as the adhesion breaks up here and there, showing that a state of pretty strong tension prevails in the thoroughly dry paper and the coat of albumen until these can break loose from their support.

The tension is apparently strongest in the albuminous coating of the paper, since the paper curls in towards that face when it is liberated; and if the process of separation is observed on the face of the print, through the glass, the still adhering white parts of the paper have a greenish, and the loosened parts the ordinary yellowish tinge of such papers, in very perceptible contrast with each other. When well dried spontaneously in a warm, dry place, if, also, the rough back of the dry paper is rubbed smooth before gently warming it to strip it off, there is strong enough electrical attraction between the glass and the released paper to keep the latter flat against the glass while the separation spreads, with clicks and snaps of freeing from the edges, until soon, the tension in the film prevailing, the glazed and loosened print bulges upwards in the middle and its ends curl inwards. In the drum-like shape which it then sometimes assumes I have seen it rolling about on the under side of the warm glass plate, supported there for some minutes by the mutual electrical attraction between the dry paper and its glass support.

After trying in vain, for some months past, to see any luminous signs of this strong electrification, by taking the warmed plate when separation was commencing, into an adjoining darker room to watch the operation's progress, to-night, at last, the experiment has perfectly succeeded. The conditions in which it did so were not exceptionally favourable ones in any particular respects that I could notice, but a quickly toned, fixed and washed albumen paper print had dried slowly and thoroughly in a dry, warm place without loosening itself from the glass surface. The paper was not smoothed on the back before holding it pretty close to the dull hot coals of a low fire, which had scarcely time to more than slightly warm it, when clicking sounds announced that splitting from the glass surface had commenced.[1] A glance through the glass face showed that loosening from the glass at one end of the print had just begun, and the plate was immediately taken, for the paper to finish freeing itself, into perfect darkness in another room. Though but very slightly warmed, a little waving of the plate, with its transparent glass side upwards, up and down (which assists the parting by rapid drying and changes of temperature in the paper), presently advanced the cleavage a little step further, and this was marked by an audible snap, and at the same time by a light-flash at the released end of the print, bright enough to have been seen easily by sufficiently watchful eyes, from any part of the moderately large room. The same bright glow followed the line of yielding of the print, while it was then quickly seized by its loose end and stripped from the under side of the glass plate by hand, as a yellow or orange-coloured stripe of gauzy light, about half an inch wide, as bright as the first flicker of whiter gauzy light.

Considering that the tough coating of dry albumen seems to be stretched on its glass support with considerable strain and force of tension, which is slackened and released immediately behind its advancing line of severance from the rigid glass, perhaps the electric excitation may be due to friction of small rubbing surfaces of the loosened coat of albumen against the glass; and in that case the example may be one of electrification by a mechanical, rather than by a molecular form of cleavage like that observed in crystals, of one surface from another. In Becquerel's well-known experiment of the evolution of electricity and light when a thin lamina of mica is split into two thinner leaves, no definable forces of released tension, leading to electrification by friction of dissimilar portions of the crystal, can be resorted to as probable effective working sources in the mica, or in other crystals, of the electricities developed by their cleavage. But while no evident condition seems, in fact, to predetermine which of the two halves of a split leaf of mica should be found to receive a positive and which a negative charge from the electrifying forces which the cleavage exercises, the common experience that glass rubbed with silk is positively, and the silk negatively, electrified in a determinate and certain way could easily afford a test, and might furnish some assurance of the sufficiency of the above view's account of the origin in mechanical friction of the glass's and paper's opposite electrifications, if the two bodies, stripped asunder, are found to be endued with electrical charges of invariable kinds agreeing with those which glass and dried white of egg acquire when they are rubbed together. But I have not yet had an opportunity of putting the question to this test by the simple use of an electroscope, although the experiment could be easily performed with that appropriate equipment as the persistency of the charges on the glass and on the paper is plentifully long enough to allow of their complete investigation.

[1] These sounds are chiefly due to tough adhesions common at ragged points along the paper edges, and overcome from time to time by the spreading separation and increasing tension. Across the open print surface the separation spreads silently and smoothly, except across occasional spots of softened albumen with unduly tough adhesion, which may also there sometimes occasion snapping sounds in parting.

The momentary gleams of the electric light-play can be very easily observed by holding an albumen paper print thoroughly well self-dried on glass, paper side downwards, in a perfectly dark room over a hot room-stove to produce the paper's separation, and by stripping the print off downwards as soon as some edge of it has grown loose enough—probably with some signs of light—to allow it to be taken in the fingers. I have by this means now seen those brush and glow lights' flitting beams a second time, and there seems to be no difficulty of producing them in varied form and brightness by this method of proceeding. A. S. HERSCHEL.

Observatory House, Slough, December 10.

Photography of the Static Discharge.

The accompanying photograph of the spark of a large static machine may possibly be of some interest to the readers of NATURE. The machine is a large Holtz, used in the electrical department of St. Bartholomew's Hospital. It consists of eight glass plates of twenty-nine inches in diameter, inclosed in a glass case. It is driven by a motor which is worked by the 100 volt alternating main which supplies the electrical department with its alternating current. The initial charge is obtained from a small Voss machine which is inclosed in the case of the Holtz. The photograph was obtained in the following manner. The machine was started and the brass knobs of the conductors adjusted to give a spark of about seven inches in length. The knobs were now tested in the usual way (by presenting a metallic point to the conductors) with reference to the

sign of their charge. A gelatine dry plate was then taken, inclosed firstly in an orange and then in a black envelope. The plate was placed between the knobs of the conductors in a line parallel with them and the sparks allowed to play over the envelope for a period of one second of time. The plate was then taken to the dark-room, developed and fixed in the ordinary way. The accompanying illustration shows the curious results obtained. A distinct break can be seen in the continuity of the sparks between the positive and negative poles. Round the positive pole the sparks are rushing off in a dense mass with a direction from the negative pole of the machine. At the line of separation of this dense mass of sparks is seen a depression as if the mass had been eroded by the negative charge, reminding one very forcibly of what happens to the positive carbon of the arc light. At the negative pole the sparks are much less dense and more fan-shaped, and radiate in the reverse direction to the positive sparks with the exception of a cone of sparks, which are much smaller, which approach the depression in the positive mass. This prolongation of small sparks towards the positive pole is seen in each of the photographs obtained. The results of the experiment are curious. I am unable to explain them, but think they are perhaps worthy of record.

St. Bartholomew's Hospital. HUGH WALSHAM.

Malaria and Mosquitoes.

As I was reading the very interesting article by Dr. Fielding-Ould on the "Malaria Campaign," which appeared in NATURE of November 8, I was struck by the fact that the use of the mosquito-netting he suggests as an efficacious preventive against malaria fever was already arrived at several years ago through nothing but experience in one of the malaria districts in Syria. The following is a translation of a letter published in vol. viii. (April 1884) of the *Muktataf*, an Arabic literary and scientific review, edited in Cairo, Egypt, by Drs. Sarrûf and Nimr:—

"To the Editors of *Al-Muktataf*.

"GENTLEMEN,—I have already had the chance of observing the spread of the malaria fever in Rashiya, both in the autumns of 1878 and 1883, and I noticed that one of the principal agents in effecting its spread was the mosquito. I have also noticed that all those who, at the time of the epidemic, took precautions against the mosquito bites escaped the fever, a fact well known in this part of the country. I therefore conclude that mosquito nets which completely cover the bed and prevent the entrance of mosquitoes are the best fever preventives in countries abounding in malaria marshes.

ABDELLA JABBOUR,

Rashiya.

Trusting the above will find a place in your esteemed paper,

N. Y. SARRÛF.

Cairo, December 7.

Can Spectroscopic Analysis Furnish us with Precise Information as to the Petrography of the Moon?

THEORETICALLY I think we may reply in the affirmative, but whether our means of observation are, as yet, delicate enough to give give us trustworthy results I leave to the investigation of your readers.

As the question is of considerable interest, pardon me if I enter somewhat into detail.

(1) If we had two smooth, plane, parallel mirrors, perfectly elastic, and a gas jet midway between them, we might first light the gas and then extinguish it without destroying the illumination, for, if the mirrors were perfectly elastic, the waves of light would oscillate between the two for ever with undiminished intensity. We know that this is not the case, therefore no known substance is perfectly elastic.

(2) If direct solar light fall upon a large mass of sandstone, part of it penetrates the mass as heat, and part is reflected, with a diminished velocity, so that we might expect, *a priori*, an apparent displacement of the Fraunhofer lines, as compared with the spectrum of direct sunlight.

(3) Similar results might be looked for with regard to limestone, basalt, &c., but not identical, unless we make the very improbable supposition that all solids are equally elastic.

(4) Hence it should be possible to construct a table of relative photo-elasticities so that if the substance were given its elasticity might be found by inspection, and *vice versâ*.

(5) Next, analysing the sunlight reflected from various regions of the moon, and referring to our table, we might hope for answers to the questions

(α) Are Tycho, Copernicus and the Appenines basaltic?

(β) Is the Mare Tranquilitatis the dried-up limestone bed of a saltwater ocean, or the dried-up sandstone bed of a freshwater inland sea?

I admit, at once, that the observations suggested are of extreme delicacy, but I cannot consider them insurmountable in an age which has witnessed the proof of the regression and subsequent approach of Sirius to the solar system by this very method. W. J. KNIGHT.

Cork.

INTERNATIONAL CATALOGUE OF SCIENTIFIC LITERATURE.

AT the International Conference which met in London last June to discuss this subject, it was thought that the time had arrived when the great work of publishing a complete catalogue of all the scientific literature of the world might be undertaken with every prospect of success.

A Provisional International Committee was, therefore, appointed at the Conference to carry out the preliminary work, and this Committee reported the results of its labours to an International Council which met last week in the rooms of the Royal Society.

At this meeting, which took place on December 12 and 13, there were present:—Prof. B. Schwalbe, representing Dr. Milkau (Germany), Prof. G. Darboux, representing Prof. H. Poincaré, and Dr. J. Deniker (France), Prof. A. W. Rücker, Sir M. Foster, Prof. H. E. Armstrong and Dr. L. Mond (Great Britain), Prof. J. H. Graf (Switzerland), Dr. E. W. Dahlgren (Sweden), Prof. Korteweg (Holland), Dr. M. Knudsen (Denmark), Mr. Roland Trimen (Cape Colony), Dr. W. T. Blanford (India), Señor del Paso y Troncoso (Mexico), and M. Metaxas (Greece). Dr. Ludwig Mond represented Italy in the absence of Prof. Nasini. Sir Michael Foster was elected chairman of the meeting.

It is proposed that the annual cost of a set of seventeen volumes shall be 17*l*., and on this basis it was announced that the number of sets subscribed for by the various countries was as follows:—

	Sets.
United States of America	68
Great Britain	45
Germany	45
France	35
Italy	27
Japan	15
Switzerland	7
Sweden	6½
Denmark	6
Holland	6
Norway	5
Mexico	5
Cape Colony	5
Canada	4½
Hungary	4
Portugal	2
South Australia	2
Western Australia	1
Victoria	1

One great difficulty in starting an enterprise of this magnitude is that a large amount of capital is needed to cover the preliminary expenses and to pay for the printing of the first set of volumes, and for other work which must be done before the grants from the various countries are received, and before any sales of the volumes to the public can be effected. This initial difficulty was met by the Royal Society, which generously offered to advance the necessary capital. This offer was accepted by the International Council, which expects to be in a position to repay the sum advanced during the next few years.

The Royal Society offered to act as the publishers of the catalogue, and to sign the necessary contracts with the printers and publishing agents. This offer was unanimously accepted by the International Council, which, after carefully examining the clauses of the proposed contracts, declared its approval of them.

The three principal countries which have not yet joined in the scheme are Russia, Belgium and Spain; and the Royal Society was asked by the International Council to address the Imperial Academy of Sciences of St. Petersburg on the subject, and also to take steps to induce the other countries to join in the catalogue.

A code of instructions for the use of all who are taking part in the preparation of the catalogue was considered, and, after some amendment, adopted.

In this connection the chief point discussed was whether it is desirable to publish complete lists of new botanical and zoological species. It was decided that lists of new species should be published, and that they should, as far as possible, contain all the additions to our knowledge in this direction made within the year.

It was also decided to include translations in the catalogue, but to indicate that they are translations. Schedules of classification for the subject indexes of the several sciences were adopted.

An executive committee was appointed, consisting of the four delegates of the Royal Society and the representatives of the four largest subscribers to the catalogue—France, Germany, Italy and the United States. Dr. H. Forster Morley was appointed director of the catalogue.

Finally, it was resolved to begin the work on January 1, 1901, and to include in the catalogue all literature published after that date.

FURTHER REMAINS FROM LAKE CALLABONNA.[1]

THE undermentioned Memoir is the second of a series, dealing with the remains of the great extinct vertebrates discovered in the Lake Callabonna in South Australia during the expedition already commented upon in our pages (NATURE, vol. lxi. p. 275, 1894), and now famous for having yielded the materials for a fuller knowledge of the osteology of the remarkable marsupial, colossus Diprotodon. The present contribution deals entirely with the great flightless bird Genyornis, which was found in association with this, and is for the most part an extended and illustrated account of portions of its skeleton, which the authors have already more briefly described in the Transactions of the Royal Society of South Australia and elsewhere. It is divided into two parts, a first dealing with the bones alone, a second containing an account of the surroundings and physical features of the Lake and the characters of its bed, of its geology, and the history of its investigation, all of which are special and detailed, and have for the greater part received prior consideration in our pages in the aforementioned article and in its predecessors therein referred to by the authors themselves (NATURE, vol. l. pp. 184 and 206), permission to quote freely from which they herein acknowledge.

It is with the first part of the Memoir we are chiefly concerned, and the newer facts it sets forth are the outcome of the results of comparison with the numerous remains described of those of allied genera mostly preserved in the Australian Museums. In dealing with these the authors pay a just tribute to the work and energetic enthusiasm of Mr. R. Etheridge, junr., the indefatigable curator of the Sydney Museum, whose Memoir on the subject in the "Records of the Geological Survey of New South Wales" is taken as the basis of their inquiry; and, as the outcome of this portion of the work, they have been led to associate with the Callabonna genus certain skeletal fragments, previously collected in South Australia, Queensland, and New South Wales, of Pliocene and Pleistocene age, especially a portion of a tibia from Mount Gambier, of a femur and some tibiæ from Normanville, of a tibia from the Paroo River, and of a fragment of a pelvis from the Canadian Gold Lead in New South Wales, most of which had been referred by Owen and Etheridge, junr., to the genus Dromornis.

The generic name Genyornis is expressive of the great size of the lower jaw, and a fuller description of this is, we presume, reserved for a promised detailed memoir in course of preparation. The present one treats mainly of the limb-bones, shoulder girdle and sternum, and the most noteworthy facts recorded are the numerical reduction of the phalanges of the outermost (fourth) digit to four, and the great slenderness, indicative of reduction, of the innermost or second, which, for the Ratitæ, are exceptional features. These characters notwithstanding, the authors, from a careful study of the measurements of the long bones and particularly of all that concerns the sternum, which is here for the first time fully described, regard the Emeu as the nearest living ally of this aberrant genus, and to the justice of

[1] "Fossil Remains from Lake Callabonna." Part II. (1) Genyornis Newtoni. (2) The Physical Features of Lake Callabonna. By E. C. Stirling, F.R.S., and A. H. C. Zeitz, C.M.M.Z.S. (Mem. Royal Soc S. Austr., vol. i. Part 2, pp. 41–80 and i.–xv., 6 photographic plates, 1900.)

their decision their photograph of the sternum, which is typically Dromæan, alone gives ample support.

Other remarkable features are the slenderness of the tarso-metatarsus and lower portion of the tibio-tarsus, and the general feebleness of the digits, the ungual phalanges of which are small, and believed to have borne "flattened nails rather than sharp and powerful claws, which could have been of little service for scratching purposes," the whole pedal skeleton, in fact, being in striking contrast with the massive proportions of the upper-leg bones and sternum. There is a moderate fibula well preserved.

Two small fragments of the coraco-scapula and some three or four ribs are described. Of the carpus there is no trace, and doubt besets a small bone referred to as a possible phalanx of the fore-limb. Concerning the anti-brachium, however, the radius and a possible ulna are preserved; and for the former the authors give measurements which show that, in contradistinction to that of all other Ratitæ, it far exceeds the humerus in length—a feature in respect to which the Emeu comes most nearly approximate but is still a long way behind.

Of remains in good preservation, or that, by the ingenious method of preparation adopted, upon which we have already commented (NATURE, vol. lxi. p. 276), could be rendered serviceable, those of the tibio-tarsalia were by far the most numerous; and in the present memoir the authors devote special attention to chemical action brought to bear upon those bones found nearest the surface, to which is due their friability and peculiar texture, associated with the formation of crystals, mostly of halite, admixed with gypsum, glauberite and alunite, by which they had become impregnated. The Memoir gives promise of further interesting results, and any one at home desirous of examining the remains will now find in the Geological Department of our National Museum at South Kensington a fine example of a hind-limb, in which the extraordinary diversity in bulk of the opposite ends of the tibio-tarsus, and the still more noteworthy slenderness of the innermost digit, must be seen to be appreciated.

SOME EXPERIMENTS ON THE DIRECT-CURRENT ARC.

ON Thursday last, December 13, Mr. W. Duddell read before the Institution of Electrical Engineers a paper on "Rapid Variations in the Current through the Direct-Current Arc," which he illustrated by experiments. Members of the Institution have already learnt from the experimental demonstration given by Mr. Duddell in 1898, when he read the paper by Dr. Marchant and himself on the alternate current arc, to expect from him most interesting experiments. Nor were they disappointed last Thursday. It is perhaps too much to say that the experiments then shown excelled in beauty and interest those exhibited on the former occasion, but they fully maintained the same high level of excellence.

Mr. Duddell has been carrying out experimental research on the arc for the past five or six years, and during the last two has, we understand, completed a series of experiments on the vexed question of the resistance of the arc. The questions dealt with in the paper read last Thursday were mainly side issues which had cropped up in the course of these researches. They embody, however, a number of most interesting and important results, many of which are suggestive of great possibilities.

The paper was divided into two parts, the first dealing with those cases in which the cause of the variation of the current was in the circuit outside the arc, the second with the cases where the cause was in the arc itself. Under the first heading, Mr. Duddell gave the results of experiments which he had made on the rapidity with which the P.D. between the electrodes of the arc, and the light emitted by the arc itself and the crater on the positive carbon, can follow variations of the current. The results show that the rapidity is surprisingly great. It is well known that with ordinary slow variations of the current through an arc a rise in current is accompanied by a fall in P.D. If the conditions of the arc were to remain unchanged, the P.D. would rise with a rise of current; but Mr. Duddell has found that the conditions of the arc can change as rapidly as 5000 times a second or more, and that when the current through an arc between *solid* carbons is suddenly increased it is only for the first 1/5000th of a second that the P.D. rises with the current. Messrs. Frith and Rodgers endeavoured, in 1896, to find the resistance of the arc by superimposing on a direct-current arc an alternating current having a frequency of 250 alternations per second, and measuring the change in P.D. thereby produced on the assumption that at this frequency the conditions of the arc did not change. The results of Mr. Duddell's work show that a frequency of at least 5000 alternations per second must be employed before such an assumption is justified.

It is remarkable also to find that the light emitted by the arc is affected by such small and rapid variations as Mr. Duddell found was the case. The light emitted by the crater and the vapour column varies sufficiently distinctly for a photographic record to be obtained even when the frequency of the superimposed variations in current is as high as 4300 alternations per second, and the amplitude of the variation as low as 3 per cent. of the mean.

When the current through the arc is altered, a change in the cross section of the vapour column is caused; and these changes, when the variations are rapid and periodic, give rise to audible sounds. Mr. Duddell has found that a variation of the order of one part in 10,000 from the mean current will alter the vapour column sufficiently to produce sound-waves. In this way an arc may be made to act as a telephone receiver by causing the varying currents in a telephone circuit to pass through the arc. An experiment was shown at the meeting in which the arc in the meeting room was used as a receiver for telephone currents from a transmitter spoken into in the basement of the building. The sounds were distinctly audible throughout the room, though the words could hardly be distinguished beyond a distance of some 10 or 12 feet. These results were obtained with a cored carbon arc—some 20-30 mm. in length and with a current of about 10 ampères.

The second part of the paper, dealing with changes of current produced by the arc, was full of interest and importance, and was illustrated by some very striking experiments. Mr. Duddell first described some experiments on the humming arc, in which he had found, by means of curves obtained with his oscillograph, that the P.D., current, and light emitted by the arc varied with the same frequency, this frequency being identical with the pitch of the note emitted. With the hissing arc Mr. Duddell finds a double variation—a large slow one, which is due, he considers, to the rotation of the arc as a whole, on which is superimposed a small rapid variation in the P.D. and current corresponding with the variation of the light emitted by the crater, this variation being produced, as Mrs. Ayrton has shown, by air obtaining access to the surface of the crater.

Perhaps the most remarkable points brought out by Mr. Duddell in his paper were those relating to the effects produced by shunting the arc with a condenser and self-induction. He has shown that the arc, if it be formed between *solid* carbons, when so shunted immediately becomes intermittent and emits a musical note. Mr. Duddell was led to this discovery by attempting to use the arc as a generator of alternating current by

rendering it intermittent by blowing it with a magnet. This method did not answer, as the intermittence was too irregular; and in order to try and overcome this irregularity Mr. Duddell shunted the arc with a condenser, and found that the arc immediately became intermittent without any blowing, and emitted a musical note. It appeared that the leads from the arc to the condenser possessed appreciable self-induction, and that if this were destroyed the musical note ceased. It thus became evident that a direct current arc between *solid* carbons, when shunted by a capacity in series with self-induction, supplied alternating current to the shunt circuit—the complete circuit consisting of the arc, self-induction, and capacity in series, the arc thus acting as a converter of direct into alternating current energy.

This effect can only be produced when the arc has the ratio of a small change in P.D. (∂V) to the corresponding change in current (∂A) *negative;* and when this ratio $\partial V/\partial A$ is numerically greater than r, the resistance of the condenser circuit. This was proved by Mr. Duddell with two experiments. With a cored carbon arc for which $\partial V/\partial A$ is positive he showed it was impossible to obtain a musical note. And using a solid carbon arc shunted by a condenser and self-induction and giving out a clear note, he showed that by increasing the resistance of the condenser circuit the sound steadily diminished and finally completely died out when this resistance became numerically equal to $\partial V/\partial A$. Any cause tending to dissipate the energy in the condenser circuit, such as, for example, the hysteresis of an iron wire core introduced into the self-induction, or any complete circuit, such as a sheet of iron or a closed ring of wire, brought near it, will also stop the note. This phenomenon suggests, as was experimentally demonstrated, a very simple and valuable method of obtaining oscillating currents of any desired frequency for experiments on magnetic space telegraphy.

Some experiments with metal arcs brought out two points of great practical importance. Mr. Duddell found that on shunting an arc between metal electrodes by a condenser the arc went out. The high rise of P.D. caused by thus suddenly breaking an inductive arc circuit may be sufficiently great to break down the insulation of the leads, as was shown by an experiment, in which a weak place in the insulation was introduced by bringing the two conductors to brass plates separated by a sheet of paper: every time the arc was shunted and put out, the paper was pierced by a spark. The same result was obtained by connecting the condenser permanently across the arc terminals and trying to strike the arc. This has important bearing on the practical use of metal switches, since it shows that the arcing at breaking should be encouraged rather than suppressed, since if there be capacity as a shunt to the switch-contacts and self-induction in the main circuit, a high rise in P.D. will occur, and may cause serious damage to the leads. As another instance of the practical application of this effect, Mr. Duddell showed that, when using an induction coil, a far longer spark could be obtained if the connections were made so that the contact maker first broke the circuit and then shunted a condenser across the gap to blow out the spark, instead of, as has always hitherto been done, having the gap permanently shunted by a condenser.

Mr. Duddell concluded his paper by showing that the note emitted by a musical arc could be tuned by adjusting the self-induction and capacity in the shunt circuit. A keyboard was arranged which shunted different capacities and self-inductions across the arc, and by this means two complete octaves were obtainable. Four arcs were arranged in series to increase the loudness of the sound, and a very distinct and not unmusical rendering of "God Save the Queen" was played on them.

The Central Technical College may well be congratulated on the work on the arc that has been done in its laboratories. Within the last two years there have been four most important papers on this subject read before the Institution of Electrical Engineers—Messrs. Duddell and Marchant's paper on the Alternate-current Arc, Mrs. Ayrton's paper on "Hissing Arcs," her paper at the Paris Congress on the "Light given out by the Direct Current Arc," and the paper by Mr. Duddell above described—all emanating from the College, and each contributing in no small degree to the elucidation of the many very difficult problems which the arc presents.

A BIRD-BOOK FOR YOUNG PEOPLE.[1]

WHETHER designedly or no, this attractive little volume is fortunate in the time of its appearance, since it forms an appropriate Christmas gift to young persons of both sexes interested in observing the ways of the birds of their own neighbourhood. And it is not even necessary that such young people should be resident in the country to appreciate the book, for the author, as in his account of the gulls on the Thames in winter, shows that there is much to be learnt with regard to bird-life even by the dweller in the metropolis. The appearance of a bird-book of this nature at the Christmas season is also appropriate in that it tends to draw attention to the severe hardships our feathered friends have frequently to suffer at this time of year, and thus attracts sympathy and attention to their wants.

To those of our readers who are familiar with the Messrs. Kearton by their previous works, no recommendation will be necessary in the case of the volume before us; while to those who have yet to become acquainted with the earlier literary and artistic efforts of these gentlemen, their new production will come as a welcome surprise. For although primarily intended for young people, it must not for a moment be supposed that the author's latest volume is not calculated to interest readers of more mature years. Indeed, the beauty and attractive character of the illustrations (two of which, by the courtesy of the publishers, we are enabled to reproduce) are alone quite sufficient to render the volume acceptable to readers of all classes and all ages. Mr. C. Kearton seems, indeed, almost to have surpassed himself, not only in the execution of the photographs, but in the interesting phases of bird-life and bird-architecture he has portrayed. All the photographs, it appears, have been specially taken for this particular volume, and as they reach one hundred in number, while their *venue* extends from the Thames Embankment to the Hebrides, some idea may be gathered of the amount of time, labour and money expended in its production.

A feature of the book is the attention devoted to nests, eggs and young birds; and although the style is essentially popular and suited to the capacity of the readers for whom it is primarily intended, older ornithologists will scarcely fail to be interested in the chapters on these subjects. In particular we may draw attention to the eight photographs on p. 99, the first of which represents a blackbird's egg on the day previous to hatching, and the other seven the young bird from day to day. By a careful arrangement and adjustment of the camera, the young bird was photographed to the same scale, and the marvellous rapidity of its development—especially between the fourth and seventh day of its existence—will come almost as a revelation to many readers. Unfortunately the further progress of the daily portraiture was brought to an abrupt termination by the unwelcome attentions of a cat. The subject is, however, full of promise, and one worthy to be taken up by other photographers.

1 "Our Bird Friends: a Book for all Boys and Girls." By R. Kearton. With photographic illustrations by C. Kearton. Pp. xvi + 215. Illustrated. (London: Cassell and Co., Ltd., 1900.)

The precautions adopted for concealing their eggs while birds are temporarily absent from the nest claim a considerable share of the author's attention; particular interest attaching to the description and illustration of the manner in which moorhens are in the habit of bending down some of the adjacent reeds in order to prevent the eggs from being seen from above. Not less attractive are the illustrations showing the contrast in the appearance of the nest of the eider-duck when just vacated by the parent bird and when the eggs are enveloped in a mantle of fleecy down. Other illustrations display the adaptation of the eggs of the plover tribe to their environment, as well as the economy in space obtained by the clutch of four being placed with their narrow ends pointing inwards, both these features being admirably displayed in the annexed photograph of a ringed plover's nest. While on the subject of eggs it may be mentioned that some confusion is, we think, likely to occur in identifying which is the raven's and which the curlew's egg in the photograph on p. 80. And it may be added that, on the same page, *Epyornis* is not the way to spell the scientific name of the extinct Malagasy roc, which is compounded from the Greek αἶπυς.

FIG. 1.—Eggs of the Ringed Plover. (From Mr. Kearton's "Our Bird Friends.")

Another subject to which the author directs the attention of his readers is the connection between the structure and form of feathers and the uses they are intended to subserve; and here, again, the illustrations admirably assist in the interpretation of the letterpress. After describing the manner in which a gannet dashes into the water in its headlong descent when in pursuit of prey, Mr. Kearton proceeds to observe that "the shock produced by such a heavy bird suddenly striking the surface of the ocean after descending from a considerable height at great velocity would kill some species of smaller size on the spot. But the gannet has been properly equipped for its task. The shafts and vanes of its breast feathers have been tremendously thickened, and their quills are buried in a quarter-inch-thick pad of very close-set down, which acts like a buffer when its wearer strikes the surface of the sea."

Contrasted with this are the "fluffy" and loosely-attached feathers on the breast of the heron, which fishes while standing, and therefore needs no breast-plate.

In his preface the author tells his young readers how, when a child, he was delighted by bird-stories told by his grandfather. "They," he adds, "will enjoy a great advantage over me in being able, through the achievements of my brother's camera, to examine accurate pictures of the birds living, loving and labouring amidst their natural surroundings." No words of ours can add aught to this modest description of the most attractive feature of a charming book.

R. L.

HUXLEY MEMORIAL.

WE have received a copy of the final report of the Huxley Memorial Committee, which announces the completion of their task, and is accompanied by a full donation list, signed on behalf of the committee by the Hon. Treasurer and Secretary. It shows the cost of the statue to have been 1814*l.*; of the dies for the medal 264*l.*, inclusive of all that pertained to each; and this, with the sum of 201*l.* for total working expenses, and the balance of 1126*l.*, paid to the Board of Education as an endowment for the medal at the Royal College of Science, brings the total amount received and expended to a little over 3450*l.*, as compared with the Owen Memorial, which realised 1100*l.*, the Darwin rather more than 5000*l.*, and the Jowett about 10,000*l.*

The statue we have already described (NATURE, vol. lxii. p. 12), and of the medal for the Royal College of Science and the arrangement for the production of a memorial medal at the Anthropological Institute, to which we alluded at the same time, the report contains nothing that is new. It concludes with the thanks of the committee to the Hon. J. Collier for the gift of a portrait of the late Prof. Huxley to the National Portrait Gallery, in lieu of their inability to provide one.

The number of persons of distinction of all nationalities who ultimately consented to join the "General Committee" was close upon 750, and of these one-third were foreigners, 33 colonials. All but 60 of them subscribed; and the total number of contributors was

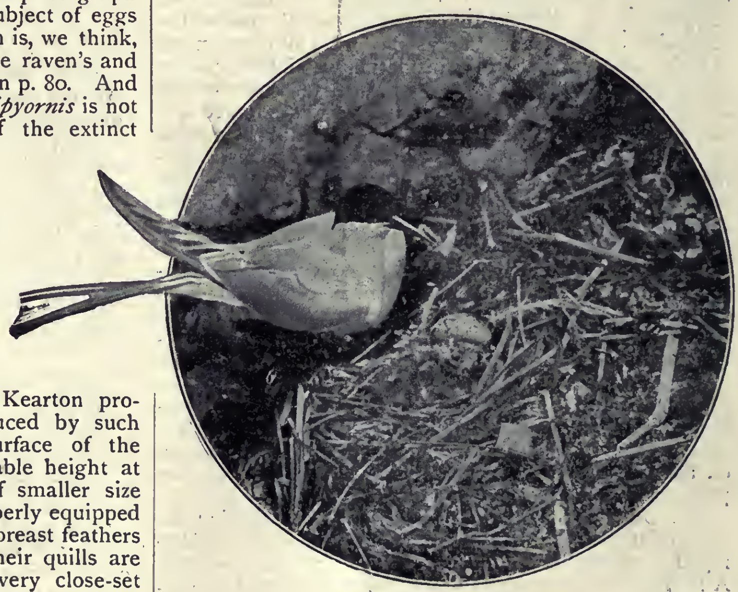

FIG. 2.—Arctic Tern guarding her nest. (From Mr. Kearton's "Our Bird Friends."

901, exclusive of local committees, societies, institutions and field clubs, each of which embraced a number of donors, and of which there were 22, making in all a total of 923 entries on the list, and of over 1000 individual subscribers. The sum raised by local subscription was 351*l.* Leeds heads the list with 54*l.*, Calcutta follows with 51*l.*, the New York Academy with 50*l.*, New Zealand contributes 30*l.*, Leicester 25*l.*, South Australia 21*l.*; and these, with Boston, U.S.A., Bristol, Cheltenham, Chester, Chicago, Chili, Ealing, Nebraska, New South Wales, New York, Paris, Servia, St. Petersburg, Upsala, Warrington, and Washington, embrace the chief colonies and centres in this way represented, together with the National Sunday League and the students of the Royal College of Science. The list includes the names of individuals resident in extreme latitudes and on the opposite sides of the globe, the sums contributed ranging from 100*l.* to half-a-crown.

The Executive Committee (of which we published a list in NATURE, vol. liii. p. 186) held twelve meetings, under the chairmanship of Lord Shand, and duly appointed sub-committees of their number for the carrying out of details. Of the subscribers, 48 died during the interval of payment and publication of the list, and of the executive, two—viz., Sir E. Frankland and Sir W. Flower, passed away before the completion of their task. Four members did not attend a meeting at all.

Concerning the statue, it may be placed on record that the late Prof. Max Müller early expressed in writing the desire that Huxley and Tyndall should be memorialised together, as are Goethe and Schiller at Weimar.

The medal, which we have not before described, bears on the obverse a profile portrait, with name in full and dates of birth and death; on the reverse a female figure with a lighted lamp in the left hand, and a laurel wreath in right, which she is about to deposit on an altar bearing the word ΕΠΙΣΤΗΜΗ, the whole backed by the foreshortened façade of the Royal College of Science. The designs for the medal were obtained by prize competition, and of the sixty-two persons who applied thirty-four competed. The premiated designs were twice the diameter of the dies (viz. 5 inches), and silver replicas of them, presented to the Royal College of Science, hang in Huxley's work-room, now a research laboratory bearing his name, beneath his portrait by Legros, and surrounded by personal relics and his working scientific library and effects, in themselves second to no memorial to his labours.

Specimen copies of the medal have been presented to Mrs. Huxley, to the British and South Kensington Museums, and, conjointly with an enlarged copy of the obverse, to the Royal Society, for their respective collections. By purchase at the cost of production, there have been acquired two sets of impressions by continental museums, and copies of the obverse in various sizes, to the number of thirty-six, by subscribers to the fund in many parts of the world.

Among the proposals for the once contemplated third object of memorial, of which the amount subscribed did not admit, there were submitted in writing suggestions for a Studentship (1) at the Royal College of Science; (2) at the Zoological Gardens, in recognition of Huxley's services to the Society, and of his connection with the foundation of its Prosectorship; for (3) a Scholarship at one of the Universities, to be open to all boys of the United Kingdom, and under the control of the Royal College of Surgeons (with an offer of 50*l.* if acted upon); for a Professorship (4) of Anthropology, and (5) of Hygiene; and (6) for a silver medal to the size of the original design for award by the Royal Society.

NOTES.

THE following have been nominated presidents of sections for the Glasgow meeting of the British Association, September 11–18, 1901: A (Mathematical and Physical Science), Major P. A. MacMahon, F.R.S.; B (Chemistry), Prof. Percy Frankland, F.R.S.; C (Geology), Mr. John Horne, F.R.S.; D (Zoology), Prof. J. Cossar Ewart, F.R.S.; E (Geography), Dr. H. R. Mill; F (Statistics and Economic Science), Sir Robert Giffen, K.C.B., F.R.S.; G (Engineering), Mr. R. E. Crompton; H (Anthropology), Prof. D. J. Cunningham, F.R.S.; I (Physiology), Prof. J. G. McKendrick, F.R.S.; K (Botany), Prof. I. Bayley-Balfour, F.R.S.

IN accordance with a resolution which was passed by the General Committee of the British Association at the annual meeting held last September at Bradford, the Council of the Association have recently considered the advisability of establishing a separate section for education. We are informed that the Council have decided that a section of educational science shall be established, but that the section shall not necessarily meet each year. The first meeting of the section will be held at the Glasgow meeting, which will commence on September 11, 1901.

FOR the purposes of a National Physical Laboratory, the Queen has granted to the Royal Society Bushey House, Bushey Park, which was formerly occupied by the Duc de Nemours.

THE Linnean Society has undertaken the collection of title-slips for the United Kingdom of Great Britain and Ireland as regards botany for the International Catalogue of Scientific Literature. All botanists are asked to support the endeavour to compile a complete record. Societies and other publishing bodies are requested to help by sending their issues as soon as possible after publication, either by gift, loan or exchange, so as to co-operate in producing a yearly record of botanic literature throughout the world. Communications for the catalogue should be addressed to Mr. B. Daydon Jackson, Linnean Society, Burlington House, London, W. Other scientific societies will, we presume, render similar assistance to the work of the International Council.

A FEW weeks ago the new anthropological collections in the American Museum of Natural History in New York were opened to the public, and these valuable collections now occupy five halls, and others are being provided. We learn from our contemporary, *Science*, that the accessions to the anthropological collections of the museum obtained during the last three years have largely been due to extended scientific research undertaken by the institution. In this respect the methods of the American Museum of Natural History differ considerably from those pursued by a number of other institutions. It has not been the policy of the museum to accumulate rapidly and indiscriminately more or less valuable specimens collected on trading expeditions or purchased from dealers; but an endeavour has been made to build up representative collections and to obtain, at the same time, the fullest and most detailed information in regard to specimens, so that each addition to the exhibit of the museum can be made thoroughly instructive and will represent a material contribution to science. There is no doubt this is the best way to build up a museum, and it is to be deplored that the various museums of the British Islands do not follow the example so worthily set by this and other American museums. Our English method is rather to wait like a spider in its web in the hope that something will eventually be caught; in the meanwhile, other institutions are intelligently collecting wholesale in diverse interesting regions, while we are content with occasional specimens which usually have no history, or at most a very imperfect one, and for these we often have to pay a stiff profit to a dealer.

King Oscar of Sweden and Norway has given a sum of 0,000kr. towards the archæological researches of Dr. L. Kjellberg in Asia Minor and the island of Lesbos.

Dr. E. von Drygalski, leader of the German Antarctic Expedition, has been elected an honorary corresponding member of the Royal Geographical Society.

Prof. Arthur Thomson, professor of human anatomy in the University of Oxford, has been elected professor of anatomy in the Royal Academy.

M. Painlevé has been elected a member of the section of geometry of the Paris Academy of Sciences in succession to M. Darboux, who has been appointed permanent secretary for the sections of mathematical sciences.

A School of Forestry has been established in connection with Yale University, under the direction of Prof. Toumey. Its home will be the residence and grounds of the late Prof. Marsh, which he bequeathed to the University for a botanical garden.

The Botanical Department of the British Museum has recently acquired M. Bescherelle's herbarium of exotic Musci and Hepaticæ, consisting of 14,800 specimens of the former and 3500 of the latter family. It contains a very large number of type-specimens.

Prof. B. D. Halsted has been elected president of the Botanical Society of America for the coming year. The *Botanical Gazette* states that an important step has been taken by the Society in appointing a committee to consider the best means of realising the purposes of the Society in the advancement of botanical knowledge. Among other matters the committee will consider the uses to which the accumulating funds of the Society may be put.

A kinswoman of Faraday has made over to the Browning Settlement a ten-roomed house at East Dulwich, to be used as a home of rest and change for the poor, and to be called the Michael Faraday Home. To fit the Home for permanent use, the sum of 150*l.* will have to be spent on alterations and repairs. The annual cost of maintenance and hospitality will be at least 100*l.* To meet this outlay an appeal has been made for funds, and it is hoped that men of science will give their support to an object which would have had the sympathy of Faraday, and which will stand as a memorial to him in his native parish. Subscriptions should be forwarded to the Warden, Robert Browning Settlement, Walworth, London, S.E.

We see in the *Athenaeum* the announcement of the death of Dr. William King. In 1857, after graduating at Galway, Dr. King went to Calcutta to join the Geological Survey Department of India, where he spent thirty-seven years, during the latter six of which period he was Director of the Geological Survey Department of India, having succeeded Dr. Medlicott. During the seven years of his directorship considerable progress was made by the Survey in the prospecting and development of the coal, oil and tin areas of the Punjab, the North-West Provinces and Burma, and in the elucidation of the complicated geological structure of the North-West Himalayan salt range and the Baluchistan formations.

A Danish expedition, composed of Lieutenant La Corn, leader, MM. Middilbo and Kofoed, physicists, and the artist Count Harald Moltke, left Copenhagen recently for Finland *via* Christiania, Trondhjem and Vadso with the object of studying the Aurora Borealis. The chief station will be established at Utsjoki, in North Finland, where the expedition will remain three months. Spectrum and magnetic researches will also be carried out. The expedition is the second of its kind dispatched under the auspices of Dr. Adam Paulsen, director of the Copenhagen Meteorological Institute.

Sir John Conroy, Bart., F.R.S., whose death at Rome occurred on December 15, will be missed in the University and city of Oxford. He was educated at Eton and Christ Church, and obtained a First Class in Natural Science in 1868. When he was elected a Fellow of the Royal Society in 1891, he was lecturer in physics and chemistry in Keble College, and an assiduous student of experimental science. Among the subjects of his contributions to science are the dioxides of calcium and strontium, the polarisation of light by crystals of iodine, the light reflected by potassium permanganate, the distribution of heat in the visible spectrum, and experiments on metallic reflection.

News has just reached us that Prof. John Gardiner, who directed the department of biology in the University of Colorado at Boulder, Colorado, from 1889 to 1898, died from consumption on November 26. Prof. Gardiner was thirty-eight years of age and a graduate of the University of London, and in 1887 he occupied the British Association's table at the Naples Biological Station. He was an enthusiastic student of biology, a man of rare culture in other lines, a fine lecturer, and was prevented from original work only by bodily weakness and the necessities of the large department over which he presided.

When observations are being made by members of the Antarctic expeditions next year, it is important that as many similar and simultaneous observations shall be recorded in North Polar regions. Several Arctic expeditions will probably be in the field, and the leader of one of them, Mr. E. B. Baldwin, who has recently arrived in England, is making arrangements to carry on as much scientific work as is practicable for a private expedition. In an interview with Reuter's representative he stated that as Lieut. Peary and Captain Sverdrup are both in Greenland, his Polar route will probably be by way of Franz Josef Land. The expedition will number at least twenty to twenty-five men, mostly Americans. Two ships will be employed in the expedition, one to return home after the Arctic regions have been entered, and the other to proceed as far north as possible. Both will start at practically the same time. These vessels will be of the whaler type, such as are usually employed in Arctic work. The exact date and point of departure of the expedition will depend upon the developments of the coming spring with regard to Peary and Sverdrup.

Replying to questions asked by Mr. Seton-Karr in the House of Commons on Thursday last, Viscount Cranborne said that regulations for the preservation of wild animals have been in force for some time in the several African Protectorates administered by the Foreign Office as well as in the Sudan. The obligations imposed by the recent London Convention upon the signatory Powers will not become operative until after the exchange of ratifications, which has not yet taken place. In anticipation, however, steps have been taken to revise the existing regulations in the British Protectorates so as to bring them into strict harmony with the terms of the convention. The game reserves now existing in the several Protectorates are :—In (*a*) British Central Africa, the elephant marsh reserve and the Shirwa reserve ; in (*b*) the East Africa Protectorate, the Kenia District ; in (*c*) Uganda, the Sugota game reserve in the north-east of the Protectorate ; in (*d*) Somaliland, a large district defined by an elaborate boundary line described in the regulations. The regulations have the force of law in the Protectorates, and offenders are dealt with in the Protectorate Courts. It is in contemplation to charge special officers of the Administrations with the duty of watching over the proper observance of the regulations. Under the East African game regulations only the officers permanently stationed at or near the Kenia reserve may be specially authorised to kill game in the reserve.

DR. BENJAFIELD, a medical man who has resided for the last twenty-seven years in Tasmania, described the advantages of the Colony as a health resort, at the Imperial Institute on Monday. He said that he was struck, on his arrival in Tasmania, with the almost complete absence of consumption and bronchitis, and it was now three years since he had signed a certificate of death from the former disease. Last year the rural mortality of Southern Tasmania was only 8·8 per 1000. In Hobart 2261 hours of sunshine have been recorded in one year, as against 1158 at Oxford in England. The climate of the Colony is one of the most even and excellent in the world. The atmosphere is pure, clear and crisp, and the general prevalence in the air, as indicated by the characteristic odour, of the essential oil of the eucalyptus tree, existing in abundance in the Colony, especially near Hobart, appears to exercise a direct antiseptic influence against deleterious organisms of all kinds.

WE have received from the *Deutsche Seewarte*, Hamburg, the ninth volume of meteorological observations made at stations beyond the sea. The observations are taken three times daily with duly verified instruments, and form a very valuable contribution to the climatology of various distant parts of the globe. Some of the stations in Labrador have been in regular operation since the time of the international polar expeditions in 1882–3, and are the more important as they lie in the track of the barometric depressions which pass from the Canadian shores into the Atlantic. Wherever the German nation gets a footing abroad, scientific investigations, and especially meteorological observations, are undertaken; in addition to the stations in Labrador, the present volume contains observations at Tsing-chow, Apia, Nauru (Pleasant Island), Ralum (New Pomerania), Mogador, and several stations on the west coasts of Africa. Observations are also being made in the German East African Protectorate, and will, it is hoped, be published in the next parts of this useful work.

THE November issue (vol. vi., No. 2) of the *Journal* of the Marine Biological Association of the United Kingdom contains an extremely interesting and important report on the fauna of the Salcombe Estuary, which has been drawn up by Messrs. E. J. Allen and R. A. Todd, with the assistance of several specialists. Salcombe Harbour possesses an exceptional zoological interest in that it was the hunting-ground of George Montagu in the earlier years of the century, and is consequently the type locality for a considerable number of British marine animals. Partly for this reason and partly because previous visits had demonstrated the richness of its fauna, the harbour was selected as a promising field for a systematic zoological survey, which was undertaken during the past summer. The authors state that the present report, from which the "plankton" is excluded, "consists almost entirely of a record of facts with regard to the nature and distribution of the fauna as we have found it during the present summer, consideration and discussion of these facts and comparison with the conditions prevailing in other localities being held over until further investigations on a similar plan have been carried out elsewhere." It does not appear that any new species were obtained.

BOTH to fishermen and to naturalists the article by Mr. W. Garstang, dealing with the plague of octopus on the South Coast and its effects on the crab and lobster fisheries, which appears in the *Journal* of the Marine Biological Association, will appeal strongly. Till the spring of 1899 the common octopus has been comparatively rare in the Plymouth neighbourhood for the last decade or so, as much as half-a-sovereign having been paid for a specimen. At that epoch, however, a marked increase in the numbers of this voracious mollusc was noticed, and during the year just closing it has appeared in such hosts as to cause widespread disaster to the shell-fish industry on both sides of the channel. Several newspaper paragraphs are quoted in evidence of the serious nature of the plague, which the author is inclined to believe is in part due to the exceptional heat of recent summers.

THE Italian earthquakes have formed the subject of a memoir by Perrey and of several detailed studies by Prof. G. Mercalli. Very numerous notices are also to be found in scientific journals, in literary and historical works, in newspapers and in books now become rare. The materials from these various sources are collected and discussed in a valuable work by Dr. M. Baratta, recently published. It consists of three parts. The first is a catalogue of 1364 of the more important earthquakes from the beginning of the Christian era to the end of 1898. In the second the seismic history of different districts is investigated, while the third contains a bibliography of more than 1600 papers, &c., on Italian earthquakes. The first two parts are illustrated by 136 seismic maps.

IN *Die Umschau*, Herr A. Stolberg gives an account of the last ascents of Count von Zeppelin's navigable balloon. The paper is illustrated by diagrams showing the modifications introduced into the construction of the machine since the earlier ascents, from which it appears that the suspended platform supporting the sliding weight used in maintaining longitudinal balance has been replaced by a latticed girder arrangement from which the weight is suspended, and, moreover, the steering arrangements have been considerably altered. The author estimates the speed of propulsion relative to the air at about 8 metres per second; and the total weight of the machine at about 10,200 kilogrammes, say ten tons.

THE latest invention in connection with wireless telegraphy is an apparatus designed to warn ships of their approach to a danger in times of fog or places where a simpler system of signalling is not practicable. The contrivance consists of a revolving wheel, having teeth of varying size, which, as it revolves, operate a Morse key connected with wireless telegraphy transmitting instruments, and according to the length of time they keep it depressed cause long or short signals to be transmitted. These signals represent the dashes and dots of the Morse code, and hence it is easy to dispose the teeth of the wheel so that any place sends out signals which spell its name. The wheel, which may be rotated by an electric motor or by clockwork, can be arranged to signal every minute or two or continuously, as desired, the idea being that it should be put into operation whenever bad weather comes on. In this way any place can be made the centre of a zone of influence, practically of any required extent, so that all ships coming within it will be notified of the fact by the ringing of an electric bell and the reception of a message giving the name of the place, provided they are fitted with apparatus for detecting the electric waves.

MR. GUSTAV FISCHER, Jena, has commenced the publication of the second revised and enlarged edition of Prof. A. Lang's "Lehrbuch der vergleichenden Anatomie der wirbellosen Thiere." The new edition will be in three volumes, the first containing four parts, the second three parts, and the third two. The part just issued is the first of the third volume, and in it Dr. K. Hescheler deals with the mollusca.

"Appendix No. 1," for 1901, of the Kew *Bulletin of Miscellaneous Information* consists of a list of the seeds of hardy herbaceous annual and perennial plants and of hardy trees and shrubs which, for the most part, have ripened at Kew during the year 1900. These seeds are not sold to the general public, but are available for exchange with colonial, Indian and foreign botanic gardens, as well as with foreign correspondents of Kew. No application for a share in their distribution, except from remote colonial possessions, will be entertained after the end of March.

IN the September number of the *Bulletin de la Société d'Encouragement pour l'Industrie Nationale*, N. S. Kournakow gives an account of his investigations on the alloys formed by sodium and potassium with mercury and of sodium with cadmium, lead and bismuth. The method employed was the determination of the temperature of fusion. Curves are drawn representing the variation of the temperature of fusion with the composition, and in all cases these curves are characterised by very distinct temperature maxima. In the case of the combination sodium and mercury, no less than seventy-five experiments have been carried out, each with a different proportion of the components. The maxima of temperature referred to are remarkably high—346° C. in the case of sodium and mercury, and 269·7° C. in the case of potassium and mercury, and the composition of the alloy corresponding to these temperatures is exactly represented by the formulæ $NaHg_2$ and KHg_2. The freezing-point depression curves which proceed from these temperature maxima are shown to extend through large temperature intervals. In the case of $NaHg_2$ the curve extends from 346° C. to 218° C. on addition of sodium, and to 155° C. on addition of mercury. The combinations of sodium with cadmium, lead and bismuth are also distinguished by very high temperature maxima, these being respectively 395°, 420° and 720° C., whereas the melting-points of the pure metals are Na 96°, Cd 322°, Pb 326°, and Bi 268° C. These characteristic temperatures correspond exactly with the formulæ $NaCd_2$, Na_2Pb, and Na_3Bi. The author draws attention to the similar phenomena which have been observed with the combinations—aluminium and gold, aluminium and antimony—and concludes that in these latter the aluminium functions as an alkali metal, giving rise to the same peculiarities as sodium and potassium in the alloys investigated by himself.

IN Prof. Cook Wilson's letter on the formula of inverse probability (p. 154) the following corrections should be made, though they do no not affect the fundamental argument: In line four of letter, for C_r and P_r read C_n and P_n; in line six, for p_r read p_n; p. 155, col. 2, line 13, for "in reality" read "on reality"; in penultimate paragraph, the last word, "strong," should be "strongest"; and in the eighth line from end, "the head" should read "this head." Finally, Prof. Wilson wishes $\frac{p_r P_r x}{\Sigma p P}$ (line 19, col. 1, p. 155) to read $\frac{p_r P_r x}{\Sigma p P x} = \frac{p_r P_r}{\Sigma p P}$.

FROM Mr. W. Engelmann, Leipzig (London: Williams and Norgate), the following scientific works have been received:—The third edition of A. de Bary's "Vorlesungen über Bakterien," revised and partly rewritten by Prof. W. Migula; Part i. of "Studien über die Verbreitungsmittel der Pflanzen," by Dr. M. Kronfeld, dealing with fertilisation effected by wind; and two parts of "Das Pflanzenreich," a conspectus of the vegetable kingdom, edited by Prof. A. Engler under the auspices of the Prussian Imperial Academy of Sciences. The plants described in these parts belong to the Musaceæ, Typhaceæ and Sparganiaceæ.

THE additions to the Zoological Society's Gardens during the past week include a Chimpanzee (*Anthropopithecus troglodytes*, ♀) from West Africa, presented by Captain W. G. Ambrose; a Mozambique Monkey (*Cercopithecus pygerythrus*) from East Africa, presented by Mr. W. J. Langton; a Lesser White-nosed Monkey (*Cercopithecus petaurista*) from West Africa, presented by Miss L. Harold; a Stair's Monkey (*Cercopithecus stairsi*, ♂) from the Lower Zambesi, presented by Miss J. C. S. Purves; a Green Monkey (*Cercopithecus callitrichus*) from West Africa, presented by Miss M. A. Reeve; a Duke of Bedford's Deer (*Cervus xanthopygius*, ♀) from Manchuria, presented by H.G. the Duke of Bedford; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Captain F. E. Cannot, A.S.C.; a Spur-winged Goose (*Plectropterus gambensis*) from West Africa, presented by H.E. Colonel F. Cardew, C.M.G.; a Common Heron (*Ardea cinerea*), two Mediterranean Peregrine Falcons (*Falco punicus*) from Mogador, presented by Mr. W. T. Barneby; a Kinkajou (*Cercoleptes caudivolvulus*) from South America, a Blue-bonnet Parrakeet (*Psephotus haematorhous*) from Australia, an Eupatorian Parrakeet (*Palaeornis eupatria*) from India, a Patagonian Conure (*Cyanolyseus patagonus*) from La Plata, three Caspian Terrapins (*Clemmys caspica*) from Western Asia, deposited; two Black-tailed Parrakeets (*Polytelis melanura*) from Australia, purchased.

OUR ASTRONOMICAL COLUMN.

NEW VARIABLE IN CYGNUS.—Mr. A. Stanley Williams announces in the *Astronomische Nachrichten*, Bd. 154, No. 3675, the detection of a new variable star. Its position is

$$\left.\begin{array}{l}\text{R.A.} = \text{20h. 59m. 50s.} \\ \text{Decl.} = +28^\circ\ 49'\cdot 6\end{array}\right\}(1855\cdot 0).$$

The magnitudes were obtained from measurements of photographs obtained with a Grubb 4·4 inch portrait lens, and were as follows:—

1899.	Oct.	6	...	Mag. = 9·85
		9	...	= 9·85
1900.		26	...	= 11·0
	Nov.	15	...	= 11·4
		22 (hazy)		= 11·4±.

In the same journal Prof. Kreutz gives a list bringing together all the new variables discovered during the past year.

SPANISH OBSERVATIONS OF THE ECLIPSE OF MAY 28.—A preliminary report of the observations of the total eclipse of the sun, May 28, made at Plasencia by the official party of Spanish astronomers, has just been issued by Señor Iniguez, director of the Madrid Observatory. The principal objects of the expedition were to record the times of the four contacts, to obtain photographs of the corona, and to determine the position of the green line of the coronal spectrum. The attendant phenomena, however, were not neglected. Among the larger instruments employed were an equatorial refractor of 20 centimetres aperture and 3 metres focus, a photographic equatorial of 20 centimetres aperture and 2 metres focus, a photographic telescope of 16 centimetres aperture and 1 metre focus, and a six prism visual spectroscope worked in conjunction with a cœlostat and horizontal telescope. The weather conditions were excellent, and a very graphic account of the general work of the expedition and of the eclipse itself is given. Five excellent photographs of the corona were obtained, three with the larger and two with the smaller coronagraph. It is remarked that the principal prominences were unconnected with the coronal extensions, and that in one of the photographs the streamers can be traced to a distance of about three diameters. For the green coronal line a wave-length of 5297·3 was determined, as compared with Sir Norman Lockyer's 5303·7 and Prof. Campbell's 5303·26 obtained from the photographs of 1898. Shadow bands were seen a minute and a half before totality, lying in a direction from south-west to north-east and travelling from north-west to south-east with a velocity comparable with that of a man walking, and at a distance apart of 8 centimetres. The atmosphere was so clear that the moon's disc was seen projected on the background of the corona for two minutes after the last contact. During the eclipse the thermometer in the shade fell 4° and that in the sun 8°. An interesting series of photographs is reproduced to show the reduction of light at various phases of the eclipse, and copies of the corona pictures are also included in the report. Señor Iniguez, to whom many foreign astronomers were indebted for much valuable information relating to their expeditions, is to be warmly congratulated on the admirable results of the efforts of his own party.

OPPOSITION OF EROS.—A sixth circular has been issued by M. Loewy from the Paris Observatory, containing ephemerides of 81 fundamental stars selected from the region including the trajectory of Eros during the period 1900 September–December,

intended for use in the reduction of meridian measures of the planet. The positions for 77 of these are given at intervals of 10 days, and for the remaining four polar stars daily positions.

Two other observatories have undertaken the special task of determining the co-ordinates of stars for reference—Charkow, directed by M. L. Struve, and d'Abbadia, directed by M. l'Abbé Verschaffel.

Many notices have come to hand indicating that a considerable number of successful determinations have been made, and a scheme is being considered to ensure the publication of all the combined results in such form as to be of the greatest service to the observers, and thus any one may be able to have access to the complete data.

M. de Campos Rodrigues, director of the Lisbon Observatory, writes saying that 743 observations have been made; heliometric measures have been commenced at Bamberg, by M. Hartwig; at the Observatory at Algiers 63 photographs have been taken.

Both at Paris and Algiers it has been found that an exposure of six minutes is sufficient to record stars as faint as 12·5 magnitude, and from special trials it is considered that with this exposure it is certain that a sufficient number of comparison stars will be obtained surrounding the planet. Prof. Hale has forwarded the times of observation at which Prof. Barnard has taken micrometer measures with the 40-inch Yerkes telescope, and a comparison shows that several of these, made during the first part of the night, correspond almost directly with others obtained at European observatories (Paris and Cambridge) during the second part of the night.

A letter from Prof. Comstock is also included, giving particulars for the accurate determination of the diurnal motion.

MARKING ON MARS.—A Circular received from the *Centralstelle* at Kiel announces a message from Prof. Pickering, who on December 8 received a telegram from Mr. Douglass, of the Lowell Observatory, Flagstaff, Arizona, stating that he had observed a projection on the northern edge of the Icarium Mare which remained visible for seventy minutes.

SPECTROSCOPIC INVESTIGATIONS OF GASES IN ATMOSPHERIC AIR.[1]

IN August last some tubes were filled at low pressure by an improved process with the more volatile gases of the atmosphere.[2] The air was liquefied directly from that above the roof of the Royal Institution by contact at atmospheric pressure with the walls of a vessel cooled below −200° C. When about 200 c.c. of liquid had condensed, communication with the outer air was closed by a stop-cock. Subsequently communication was opened, through another stop-cock, with a second vessel cooled by immersion in liquid hydrogen, and a part of the liquid from the first vessel, maintained at −210°, was allowed to distil into the second still colder vessel. When about 10 c.c. had condensed in the solid form in the second vessel, communication with the first vessel was cut off, and a manometer showed a pressure of gas of about 10 to 15 mm. of mercury.

This mixture of gases was passed into tubes previously exhausted by a mercury pump, but before reaching the tubes it had to pass through a U-tube immersed in liquid hydrogen so as to condense less volatile gases, such as argon, nitrogen, oxygen or carbonic oxide, which might be carried along by those more volatile. Previous trials with tubes filled in the same way, except that the U-tube in liquid hydrogen was omitted, showed that these tubes contained traces of nitrogen, argon and compounds of carbon. The tubes filled with gas which had passed through the U-tube showed on sparking no spectrum of any of these last-mentioned gases, but showed the spectra of hydrogen, helium and neon brilliantly, as well as a great many less brilliant rays of unknown origin. In addition, they showed at first the brightest rays of mercury, derived no doubt from the mercury pump by which they had been exhausted before the admission of the gases from the liquefied air. After some sparking the mercury rays disappeared, probably in consequence of absorption of the mercury by the electrodes, which were of aluminium.

In one experiment the mixture of gases in the second vessel, into which a fraction of the liquefied air was distilled as above described, was pumped out without being passed through the U-tube in liquid hydrogen and examined. This mixture was found to contain 43 per cent. of hydrogen, 6 per cent. of oxygen, and 51 per cent. of other gases—nitrogen, argon, neon, helium, &c.—and it was explosive when mixed with more oxygen. This shows conclusively that hydrogen in sensible proportion exists in the earth's atmosphere, and if the earth cannot retain hydrogen or originate it then there must be a continued accession of hydrogen to the atmosphere (from interplanetary space), and we can hardly resist the conclusion that a similar transfer of other gases also must take place. The tubes containing the residue of atmospheric gases uncondensed at the temperature of liquid hydrogen we have examined spectroscopically.

On passing electric discharges through them, without any condenser in the circuit, they glow with a bright orange light, not only in the capillary part, but also at the poles, and at the negative pole in particular. The spectroscope shows that this light consists in the visible part of the spectrum chiefly of a succession of strong rays in the red, orange, and yellow, attributed to hydrogen, helium and neon. Besides these, a vast number of rays, generally less brilliant, are distributed through the whole length of the visible spectrum. They are obscured in the spectrum of the capillary part of the tube by the greater strength of the second spectrum of hydrogen, but are easily seen in the spectrum of the negative pole, which does not include the second spectrum of hydrogen, or only faint traces of it. Putting a Leyden jar in the circuit, while it more or less completely obliterates the second spectrum of hydrogen, also has a similar effect on the greater part of these other rays of, as yet, unknown origin. The violet and ultra-violet part of the spectrum seems to rival in strength that of the red and yellow rays, if we may judge of it by the intensity of its impressions on photographic plates. We were surprised to find how vivid these impressions are up to a wave-length 314, notwithstanding the opacity of glass for rays in that part of the spectrum. The photographs were taken with a quartz calcite train, but the rays had to pass through the glass of the tube containing the gases.

We have made approximate measurements of the wave-lengths of all the rays which are sufficiently strong to be seen easily or photographed with an exposure of thirty minutes, and give a list of them below. These wave-lengths are computed to Rowland's scale, and were deduced from the deviations produced by two prisms of white flint glass for the visible, and of calcite for the invisible, rays. The wave-lengths assigned to the helium lines are those given by Runge and Paschen, and some of these lines were used as lines of reference. In general, the iron spark spectrum was the standard of reference.

The tubes when first examined showed the lines of the first spectrum of hydrogen vividly, and the earlier photographs of the spectrum of the negative pole contained not only the violet lines of hydrogen, but also the ultra-violet series as far up as λ 337. In order to get impressions of the faintest rays, exposures of half an hour or more were required, and a succession of photographs had to be taken so as to get different sections of the spectrum into the middle of the field, where measurement of the deviations would not be impeded by the double refraction of the calc spar. As the light of the negative pole only was required, the electric discharge was made continuously in one direction only, with the result that the hydrogen lines grew fainter in each successive photograph, and soon disappeared altogether. Along with the ultra-violet rays, the less refrangible rays of hydrogen also disappeared, so that no trace of the C or F line could be seen, nor yet of the second spectrum, so long as the current passed in the same direction as before. Reversal of the current soon made the F line show again, so that it seems that the whole of the hydrogen was driven by the current to the positive pole. The conditions under which this ultra-violet series shows itself are a matter of interest. It appears here in the midst of a brilliant spectrum due to gases other than hydrogen, and yet it is very difficult to obtain a photograph of it when no gas but hydrogen is known to be present, or, at least, to become luminous in the electric discharge.

We have had an opportunity of comparing the spectrum of the volatile residue of air with that of the more volatile part of gas from the Bath spring. The tube did not admit of the separate examination of the light from the negative pole, but

[1] "On the Spectrum of the more Volatile Gases of Atmospheric Air, which are not Condensed at the Temperature of Liquid Hydrogen." Preliminary notice by Prof. G. D. Liveing and Prof. Dewar.—Read before the Royal Society on December 13.

[2] In this paper we describe researches in continuation of those previously communicated to the Society by one of us, in a paper entitled "Application of Liquid Hydrogen to the Production of High Vacua, together with their spectroscopic Examination," *Roy. Soc. Proc.* vol. 64, p. 231.

was examined end on, so that the radiation probably included rays emitted from the neighbourhood of the negative pole. The whole of the hydrogen had been removed from the Bath gas, but not all the argon. In the spectrum of this gas the rays of helium are dominant, decidedly stronger than those of neon, although the latter are very bright. In the spectrum of the residue of atmospheric air the proportion of helium to neon seems reversed, for in this the yellow neon line is as much more brilliant than the yellow helium line as the latter is the more brilliant in the spectrum of Bath gas. All the prominent lines in the spectrum of the volatile residue of Bath gas were also in that of the residue of atmospheric air except the argon lines. There were, on the other hand, many lines in the latter not traceable in the former, some of them rather conspicuous, such as the ray at about λ 4664. It is, of course, probable that such rays are the outcome of some material not contained in the Bath gas. A very conspicuous pair of lines appears in photographs of the spectrum of the air residue, at about λ 3587, which is not traceable in the spectrum of Bath gas. The helium line, λ 3587·4, is seen in the latter spectrum, but is quite obscured in the former spectrum by the great intensity of the new pair. This helium ray is really a close double, with the less refrangible component much the weaker of the two, but the new pair are wider apart, and of nearly equal intensities; this character also distinguishes them from the strong argon line at λ 3588·6. They are, however, very much more intense at the negative pole than in the capillary, and it will require a good deal more study to determine whether these rays, and many others which we have not tabulated, are due to the peculiarity of the stimulus at the negative pole or to the presence of a previously unrecognised material.

As our mixture of gases probably includes some of all such gases as pervade interplanetary and interstellar space, we early looked in their spectra for the prominent nebular, coronal and auroral rays. Searching the spectrum about λ 5007 no indication of any ray of about that wave-length was visible in the spectrum of any one of the three tubes which had been filled as above described. Turning to the other green nebular line at about λ 4959 we found a weak rather diffuse line to which our first measure assigned a wave-length 4958. The correctness of this wave-length was subsequently verified by measuring with a micrometer eye-piece the distances of the line from the helium lines λ 4922·1 and λ 5015·7 which were in the field of view at the same time. The position of the line was almost identical with that of the iron spark line λ 4957·8, and the conclusion arrived at was that the wave-length was a little less than 4958, and that it could not be the nebular line. There remained the ultra-violet line λ 3727. Our photographs showed a rather strong line very close to the iron spark line λ 3727·8, but slightly more refrangible. As the line is a tolerably strong one it could be photographed with a grating spectrograph along with the iron lines. This was done, and the wave-length deduced from measuring the photograph was 3727·4. This is too large by an amount which considerably exceeds the probable errors of observation, and we are forced to conclude that the nebular material is either absent from our tubes, or does not show itself under the treatment to which it has been subjected.

Although the residual gases of the atmosphere, uncondensed at the temperature of liquid hydrogen, do not show the nebular lines, we found that another tube gave a ray very close indeed to the principal green nebular ray. This tube had been filled with gas prepared in the same way as the others, with the exception that, in passing from the vessel into which the first fraction of liquid air was distilled, it was not passed through a U-tube immersed in liquid hydrogen on its way to the exhausted tube. In consequence it contained traces of nitrogen and argon, and when sparked showed the spectra of these elements as well as those of hydrogen, helium, &c. The nitrogen spectrum disappeared after some sparking, but the tube still showed rays of argon as well as those of the gases in the other tubes. On examining the spectrum of the negative pole in the neighbourhood of the principal nebular green ray, a weak ray was seen in addition to those given by the other tubes. It was found by comparison with the nitrogen rays λ 5002·7 and λ 5005·7 to be a little less refrangible than the latter of these rays, and by measuring its distance from the nitrogen rays and from the two helium rays λ 4922·1 and λ 5015·7 with a micrometer eye-piece, the wave-length λ 5007·7 for the new ray was deduced. This looks as if we might find the substance which is luminous in nebulæ to be really present in the earth's atmosphere, and we hope shortly to be able to verify the observation of it.

Turning to the coronal rays, our tubes emit a weak ray at about λ 5304. This is not far from the wave-length λ 5303·7 assigned by Sir N. Lockyer to the green coronal ray. It is, however, greater than that assigned by Campbell, namely, 5303·26. Other lines observed by us near the places of coronal lines are at wave-lengths about 4687, 4570, 4358, 4323, 4232, 4220, 3985, 3800. These are all weak lines except that at λ 4232, which is of tolerable strength, and that at λ 4220, which is rather a strong line. The wave-lengths 4323, 4232, 4220 and 3800 come very close to those assigned to coronal rays, but the others hardly come within the limits of probable error. The ray 4220 seems too strong in proportion to the others, but the strength of that at 4232 seems to accord with the strength of the corresponding ray in the corona. It will be seen that the rays we enumerate above correspond approximately to the stronger rays in Sir N. Lockyer's list. Further measures of the wave-lengths of the faint lines are needed before we can say definitely whether or no we have in our tubes a substance producing the coronal rays, or some of them.

As to the auroral rays, we have not seen any ray in the spectrum of our tubes near λ 5571·5, the green auroral ray. We have observed two weak rays at λ 4206 and λ 4198, which may possibly, one or both, represent the auroral ray λ 420. The very strong ray of argon, λ 4200·8, would make it probable that argon was the origin of this auroral ray, if the other, equally strong, argon rays in the same region of the spectrum were not absent from the aurora. Nor have we found in the spectrum of our tubes any line with the wave-length 3915, which is that of another strong auroral line. On the other hand it seems probable that the strong auroral line λ 358 may be due to the material which gives us the very remarkable pair of lines at about the place of N of the solar spectrum, λ 3587, which are very strong in the spectrum of the negative pole, but only faint in that of the capillary part of our tubes. It may well be that the auroral discharge is analogous to that about the negative pole. We have also a fairly strong ray at λ 3700, which may be compared to the remaining strong ray observed in the aurora λ 3700. This, however, is a ray which is emitted from the capillary part of our tubes as well as from the negative pole, and is, moreover, emitted by Bath gas, and may very likely be a neon ray.

We hope to pursue the investigation of this interesting spectrum, and if possible to sort out the rays which may be ascribed to substances such as neon and those which are due to one or more other substances. The gas from Bath, even if primarily derived from the atmosphere—which is by no means sure—seems to have undergone some sifting which has affected the relative proportions of helium and neon, and a more thorough comparison of its spectrum with that of the residual atmospheric gases may probably lead to some disentanglement of the rays which originate from different materials. The arrangement of the rays in series, if that could be done, would be a step in the same direction.

The table appended to the above paper is not given here, but it consists chiefly of wave-lengths expressed in four figures only.

THE TREATMENT OF LONDON SEWAGE.[1]

WHEN, some years since, the raw sewage of London was regularly poured into the river in the neighbourhood of the city, the road detritus and putrescible fæcal matter which were delivered in the sewage settled on the river bed and foreshores. The road detritus tended to permanently reduce the depth of the river; while the putrescible matter, arriving faster than it could be removed by the river or could be destroyed by inoffensive bacterial action, accumulated as a deposit on the foreshores and floated in masses of thick scum on the river. It there underwent foul putrefactive changes, rendering the river most offensive to those who navigated it or lived and worked near its banks, and almost intolerable in summer weather, even to those who crossed its bridges. That this result was inevitable will be understood when it is remembered that the sewage consists of the whole of the water-supply and rainfall over the

[1] Abridged from a paper read before the Society of Arts, on December 12, by Prof. Frank Clowes.

metropolitan area which have been charged with varied refuse matters of our streets, our houses, and our manufactories.

The nuisance was removed by taking the sewage fifteen miles below London. Since this was found insufficient, the sewage was subsequently subjected to chemical treatment and sedimentation before it was allowed to flow into the river. The treatment ultimately adopted, and still in vogue, consists in straining or "screening" off the larger solid matters and then mixing the sewage with solutions of lime and sulphate of iron; the chemical precipitate thus produced is then allowed to settle, together with the finer particles in the sewage, by sending the sewage slowly through parallel channels on its way to the river. The settled matter, or "sludge," is sent in tank-steamers to be discharged out at sea beyond the river's mouth; and the fairly clear "effluent" passes constantly into the river from the northern outfall (Beckton or Barking) and the southern outfall (Crossness) in two streams, which jointly deliver over 200.000,000 gallons every twenty-four hours into the river, and which probably constitute the most important tributaries of the lower Thames near London. Since these processes of chemical treatment and sedimentation have been adopted, the foreshores of the river have become clean, the outrageous foulness of the stream has ceased, and those who live on and near the Thames unanimously express their approval of the improvement effected.

It must be remembered, however, that the effluent of the sewage, after it has been freed from visible foul matter, still contains in invisible solution a large amount of putrescible substance, which may, under suitable conditions, lead to serious foulness in the stream. The effluent at present discharged into the river is practically only clarified sewage. As long as putrefactive changes are delayed by low temperature of the river water, and an ample flush of upper river water comes down to dilute this effluent and to carry it rapidly out to sea, no sensible foulness occurs in the main stream. But in summer time, when high temperature hastens putrefactive change and diminishes the amount of oxygen dissolved in the river water, and when the flush of water from the upper river is diminished by drought and by the abstraction of larger volumes of the water by the water companies, the condition of portions of the lower river frequently closely approaches that necessary to cause offence. There can be no doubt that as the volume of sewage effluent increases, and the abstraction of upper river water for water-supply also increases with the increasing population, these portions of the lower river must pass more frequently into a condition bordering upon or actually causing foulness. It is, therefore, prudent to be prepared to adopt without delay a method of treatment of the London sewage which shall meet the requirements of an increasing population, and shall enable the more ample effluent to be discharged into the river in a state of greater purity than is at present secured.

As far back as 1893, the Main Drainage Committee of the County Council, on the advice of their chemist, Mr. Dibdin, started a large scale experiment on the bacterial purification of sewage, the purification being applied to the effluent from chemical treatment and sedimentation. This experimental treatment has been continued by the committee, on my own advice, and has been considerably extended in its scope. The committee also consented to the association of the eminent bacteriologist, Dr. Houston, with me in these experiments during the three years of their progress. The results which have been obtained have been published by the London County Council in the form of a series of reports which I have laid before them from time to time. The general conclusion to which they point is that the settled sewage may be purified to a far greater degree than it is by the present treatment, by encouraging the spontaneous purifying action of the bacteria which are present in the sewage itself. The effluent thus produced, without the intervention of chemicals, remains free from foul putrefaction and is able to support the life of fish; in these and in all other respects it is greatly superior to the effluent which is at present discharged into the river. The minute vegetable organisms, known as bacteria, exist to the average number of 300,000 per drop of sewage. They only require to be placed under suitable conditions in order to effect the rapid and inoffensive resolution of the putrescible matters of the sewage into harmless and inoffensive products.

The general conclusions derived from the experimental bacterial treatment of raw sewage at the out-falls of the London sewage into the Thames are as follows:—

(1) The following results were obtained by treating the raw sewage bacterially in coke-beds. In the process adopted, the sewage was allowed to flow into large tanks which contained fragments of coke about the size of walnuts. As soon as the level of the liquid had reached the upper surface of the coke-bed, its further inflow was stopped, and it was allowed to remain in contact with the bacteria coke surface for two or three hours. It was then allowed to flow slowly away from the bottom of the coke-bed. This out-flowing liquid constituted the "sewage effluent." After an interval of from three to seven hours, the processes of emptying and filling the coke-bed were repeated with a fresh portion of sewage. The coke-bed was at first filled in this way twice in every twenty-four hours, but later on it was filled three and four times in twenty-four hours.

(2) A considerable purifying action has been effected by the coke-bed. This is produced by the introduction of bacteria from the sewage. The maintenance of the purifying action is due to the presence of bacteria or their enzymes upon the coke surfaces, and to the adequate aëration of these surfaces by frequently exposing them to the oxygen of the air.

(3) The oxygen undergoes absorption by these surfaces, and the aëration of even the lowest portions of a deep coke-bed seems to be satisfactory in the above method of working, since the air present in the interstices of the coke, between two fillings with sewage, usually contains as much as 75 per cent. of the amount of oxygen present in the air.

(4) Raw sewage, which had been deprived of its larger particles by screening it through coarse gratings, lost practically the whole of its suspended matter by remaining in such a coke bacteria bed for two or three hours. It appears that the suspended particles of fæcal matter underwent liquefaction by the bacteria, since they did not collect upon the surface of the coke.

(5) The sand and grit and finer mud, arising mainly from the wear of road surfaces, however, were deposited upon the coke surfaces, and gradually reduced the capacity of the coke-bed.

(6) Hair, fibrous matter and woody fibre derived from the wear of wooden street pavements, and particles of chaff and straw mainly derived from the dejecta of horses employed in the street traffic, were also deposited upon the coke surfaces and gradually choked the coke-bed. These substances, which consist mainly of cellulose, are apparently only acted upon by bacteria with extreme slowness under the above conditions. They arrive, however, in a water-logged condition, and rapidly settle down from the sewage if its rate of flow is reduced.

(7) In dealing with the sewage of the metropolis, it seems best to submit the roughly screened raw sewage to a somewhat rapid process of sedimentation, in order to allow these suspended mineral and cellulose matters (5, 6) to subside; and then to pass the sewage direct into the coke-beds. The dissolved matters and the small amount of suspended matters which are still present in the sewage are then readily dealt with by the bacteria of the coke-bed, and no choking of the beds occurs.

(8) The sewage effluent which is thus obtained from the coke-beds is entirely free from offensive odour and remains inoffensive and odourless even after it has been kept for a month at summer heat, either in closed or open vessels. It is clear, except when a turbidity is produced by fine mud particles washed down by heavy rain. Many pond and river fish have been kept in the constantly renewed effluent for a month, and have been found to be perfectly healthy at the end of that period.

(9) The chemical character of this effluent may be briefly indicated by stating that on an average 51·3 per cent. of the dissolved matter of the original sewage, which is oxidisable by permanganate, has been removed by the bacteria, and that the portion which has been removed is evidently the matter which would become rapidly offensive and would rapidly lead to de-aëration of the river water if it were allowed to pass into the river. The above percentage removal (51·3) was effected by coke-beds varying from 4 to 6 feet in depth. A similar bed, 13 feet in depth, has proved more efficient, and has for some time produced a purification of 64 per cent., while an old bed, 6 feet in depth, has given a purification of 86 per cent. A repetition of the treatment of the effluent in a second similar coke-bed has produced an additional purification of 19·3 per cent., giving an average total purification of 70·6 per cent. (*See* Table I.). It should be noted that the above purification is reckoned on the dissolved impurity of the sewage; the suspended solid matter is not taken into account. No difficulty has been found in maintaining this bacterial purification.

TABLE I.—*Relative Impurity as Estimated by Permanganate.*

Raw sewage deprived of its suspended matter ...	3·696	Percentage purification calculated on clear raw sewage.
Effluent from chemical treatment	3·070	16·9
Effluent from single bacterial treatment	1·799	51·3
Effluent from double bacterial treatment	1·137	69·2
River water (high-tide) ...	0·550	—
,, ,, (low-tide) ...	0·429	—

(10) The bacteriological condition of the effluent corresponds in the main with that of the raw sewage. The total number of bacteria undergoes some reduction in the coke-beds, but the different kinds of bacteria which were present in the sewage are still represented in the effluent.

(11) The introduction of such a sewage effluent into the lower Thames is unobjectionable. The river water at the points where the effluent is discharged is uniformly muddy; it is always brackish and frequently salt to taste, owing to the presence of tidal sea water. It is, therefore, not capable of being used for drinking purposes. The effluent would certainly cause no deposit upon the river bed, and would ordinarily tend to render the muddy river water more clear by mixing with it. No offensive smell would be emitted by the effluent as it is discharged into the river. And, although the effluent contains more organic matter than the river water does, the bacteria which it contains would slowly and inoffensively remove this organic matter from the effluent after it has been introduced into the river. The effluent would be suitable for the maintenance of healthy fish-life.

A PRE-COLUMBIAN SCANDINAVIAN COLONY IN MASSACHUSETTS.

THE evidence in favour of a partial settlement of Massachusetts by Scandinavians is gradually accumulating, and in the current number of the *American Anthropologist* (New Series, vol. ii., p. 550), Mr. Gerard Fowke adduces new observations. He says, few persons living among the evidences of Norse occupancy have ever paid any particular attention to them, taking for granted that they are the work of the earlier generations of English inhabitants of the region. Those who give more than a passing thought to these objects of unknown origin can see at once that many features connected with them not only would have been unsuitable for any of the necessities of the latter people, as they were then compelled to live, but could not have been turned to any practical use when completed. Such a conclusion is followed at once by the inference that they must pertain in some way to the social customs in vogue among the American Indians; but it does not require an extended acquaintance with aboriginal remains to convince an observer of the error of this inference, the two classes of works being entirely different in many of their most distinctive characters.

Peculiar to the valley of the Charles river are the hut-sites excavated in the hillsides with their rows or piles of boulders to afford a resting place or foundation for the walls of the structures; the ditches that extend with practically a water level along the slopes of the hills; the dams that obstruct the river and many of its tributaries on both sides; the artificial islands walled or protected with stones; the stone walls along the margin of the streams, between high and low tide—none of these has a counterpart in any known works which can be attributed to Indian habits and life. Of very different character are the extensive earthworks in the bottom-lands; the hill-top fortifications of earth and stone; the immense tumuli of earth or stone, or both combined; and the huge flat-topped mounds of the Mississippi valley, erected by the Indian tribes popularly known as "mound-builders."

Remains of rectangular houses with very thick walls composed of stones and turf have been found of a size sufficient to accommodate several families in the old Scandinavian fashion. The long-houses of the Iroquois and some of the larger houses built

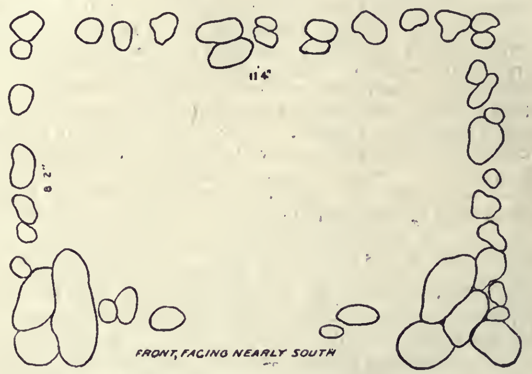

FIG. 1.—House-site above Sibley's, on opposite side of swamp, near Massachusetts Central Railway.

by the Chippewa had the same general form, but with that the resemblance ceases. No foundation was necessary in the Indian house, and it was made principally or entirely of wood and bark. Similarly, nothing at all of Indian origin is known like the cot or hillside huts, of which a number have been examined. These are made by digging back into a sloping surface until a level floor of the desired area is formed; sometimes stones were placed around the sides, in one case (Fig 1) walls of stone and turf were built along the sides. There are indications that such places were covered with timber on which earth was piled.

Near East Watertown is a large natural depression or "kettle-hole." Around two-thirds of the circumference of this, artificial terraces have been constructed, apparently to furnish seats from which spectators might view the exercises or ceremonies which presumably took place on the enclosed level area at the bottom. Somewhat more than a mile south of this "amphi-

FIG. 2 Supposed Norse grave at Clematis Brook, Charles River, Massachusetts.

theatre," at one side of a small area of smooth level bottom-land, a sloping bank rises rather steeply to a height of perhaps thirty feet; along this slope are three or four terraces, not large enough to be of any use for tillage. There is nothing in the eastern part of the United States known to be of Indian origin with which these may be properly compared.

The author describes the various kinds of burial works of the Indians, and compares the numerous cairns found in Massachusetts with Indian stone mounds, but most of these were very much larger than any cairns supposed to be constructed by the Norse. The Indian graves contain skeletons and relics. The stone cairns, the cairns in question, are called graves because they answer, in every particular of size and situation, to those mentioned in different sagas, and are in the midst of various other remains which must be attributed to the Northmen; and yet, in all that have been examined there has not been found the slightest trace of bone or any object which shows the least indication of being artificial. This, however, is only negative evidence; the same statement is true in regard to the graves of Iceland and Greenland; and not only of the graves in these countries, but also of the house-sites. It is also apparent that they differ from Indian graves even more in the manner of their interior construction than in their outward appearance. A. C. H.

PROGRESS OF SCIENCE TEACHING.

THE first report of the newly organised Board of Education has now been published. It consists of three volumes—the first contains the general report of the Board, the second is concerned only with secondary, and the third volume only with elementary education. A very important part of the second volume comprises the reports of the inspectors of the South Kensington branch of the Board of Education, who have charge of the teaching of science and art in different parts of the country. Without exception the inspectors tell a gratifying story of better equipment, improved methods, and saner ideals in the science schools visited by them. But though there has been a decided step forward there is still much to be accomplished and plenty of need for the best energies of both inspectors and teachers.

The reports are full of interesting details, it is true, yet certain broad questions touched upon by nearly every inspector are likely to be of greater general interest. The first of these the senior chief inspector, Mr. Gilbert Redgrave, refers to at some length. Readers of NATURE are already quite familiar with it—the unsatisfactory condition, that is, of the preliminary education of science and technical students in all parts of the country. Mr. Redgrave says: "I find that in a very large number of cases the work of the teacher in an evening class under this Board is crippled and rendered ineffective owing to the backward state of many of the students who enter the classes, and who are really only qualified for the evening continuation school." As Dr. Ball points out, in his report on the work of the South-Western district, the science inspector has no connection with public elementary education and consequently no means of officially acquainting himself with what provision is made for the teaching of science in the elementary school, and there can be little doubt that it is this want of continuity which is very largely to blame for the disparity between what an ex-standard scholar actually knows and what he should be acquainted with if he is to benefit by the instruction of the science class or technical school. Fortunately, local endeavour is doing something to remedy this evil. Mr. Hugh Gordon tells of an arrangement in the county of Durham by which, during the year with which his report is concerned, the County Council refused to grant aid on the attendance of students at a class in a subject unless the students could produce satisfactory evidence to show they possessed the necessary preparatory knowledge, or would attend concurrently such other classes as the teacher considered desirable. Similar instances could be cited, but this example will serve to exemplify what attempts are being made to cope with a real danger to our system of national technical education.

Another subject which very properly takes an important place in most of the reports is the need of practical instruction in all science teaching. There has, the reports show, been a decided improvement in the amount and character of the practical work in all branches of science, except, perhaps, in the case of physiography. In order to enable teachers to illustrate their lessons with properly prepared experimental demonstrations, and to foster individual practical work for their students, they must be given time in which to prepare such lessons. We are glad to see that Mr. Harold Wager calls prominent attention to this fact in his report on the Yorkshire division. He says: "The governors or managers of many of these schools have not yet fully appreciated the fact that teachers of practical science subjects require a considerable amount of time for the preparation of the experiments for their lessons beyond the time actually devoted to teaching. The necessary preparation for a good practical lesson in the laboratory is no light task, and if the work is to be done properly the teacher must have time for it."

Some progress in the direction of co-ordinating the work of the numerous local authorities for education has been made, but there still seems to be considerable misapprehension as to the precise limits of the sphere of influence of each committee or other governing body. It is gratifying to see that broad-minded counsels have prevailed in many centres, with the result that the very large amount of energy thereby saved has been devoted to the improvement of the local supply of scientific and technical instruction. Mr. Redgrave sketches a plan by which the different schools may work together in a satisfactory and harmonious manner. "The Technical School under the Town Council should be a day school for students who have passed through a course of two or three years in a School of Science, which might be conducted by the School Board, and who may desire to qualify themselves for good positions in industrial or commercial pursuits. The School of Science managed by the School Board would in each case be the preparatory school for the Technical School, but it would also provide an education complete in itself for those who leave school at the age of fifteen or sixteen. The evening classes at the Technical School should be classes in connection with the Board, or with the City and Guilds of London Institute, while the evening classes under the School Board should in all cases be those of the evening continuation school, and students should be encouraged to prepare for the classes under the Technical Instruction Committee by a course of study in the evening continuation school." Similar plans have, indeed, been already tried with great advantage in several centres, and it is much to be desired that some such sensible system of co-operation should be universally adopted.

Only part of the science teaching given in secondary schools comes within the purview of the reports under consideration, that, namely, which takes place in secondary schools receiving financial aid from the Board of Education. Mr. Buckmaster deals almost exclusively with this part of the work of the South Kensington branch of the Board. Among other matters which his report makes clear is the fact that there is likely to be some difficulty in the future in those cases where the inspector of the Board of Education and the organising secretary of a County Council Technical Instruction Committee come to different conclusions about a school after inspecting it. As Mr. Buckmaster says, "even in a county area cases may occur where the County Technical Committee will deprecate criticism on the schools it has selected as recipients of its grants."

The points of interest in this very valuable volume have been by no means exhausted by this brief notice. The chief topics only have been passed in review; the interested reader must be referred to the reports themselves for a more detailed account of a vitally important subject.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. ARTHUR ROBINSON has been appointed professor of anatomy at King's College, London.

Science states that in an address to the students of Colorado College, Dr. D. K. Pearsons, of Chicago, announced that on January 1, 1901, he would make the college a gift of 10,000*l* towards the cost of completing the new scientific building now in course of construction.

AT the close of his rectorial address at Aberdeen University on Tuesday, Lord Strathcona expressed his willingness to contribute 25,000*l*. to the University if within a year 50,000*l*. more were raised to complete the buildings and properly equip the University. Mr. Charles W. Mitchell has telegraphed to the Principal that he will be responsible for the whole of the present debt on the University buildings if it does not much exceed 20,000*l*. Mr. Mitchell is a son of the late Dr. Charles Mitchell, who was a liberal benefactor of the University.

A BASE measuring apparatus, which has been perfected in connection with the summer school work of the Civil Engineering Department of the Massachusetts Institute of Technology, has recently been tested by the Coast and Geodetic Survey in Washington. Such satisfactory results have been already obtained that the apparatus is about to be used in the important Lampasas Base in Texas. Prof. Burton, of the Institute, under whose direction the apparatus has been worked out, has been invited to accompany the expedition, which is to make a careful trial of the method in the field and upon extended exact work. The apparatus represents the final results of thesis investigations by several graduates of the course in civil engineering who have worked upon it in successive years. One part of the apparatus maintains a constant tension in the steel tape while in use. Another part of the apparatus determines very accurately the mean temperature of the tape by measuring its electrical resistance by means of a special form of thermophone devised by two graduates.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, December 14.—Meeting held at the Royal College of Science (by invitation of Prof. Rücker), Principal O. J. Lodge, President, in the chair.—A paper on electric inertia and the inertia of electric convection was read by Prof. A. Schuster. Calculations of self-induction are based on the assumption that the currents which traverse a conductor fill it continuously, the flow being treated as that of an incompressible liquid. The assumption is generally recognised not to hold in the case of electrolytes where electricity is conveyed by a number of irregularly distributed ions. In the immediate neighbourhood of such an ion, the magnetic field is many times greater than that calculated on the supposition of continuous distribution, and hence the total magnetic energy is underestimated. What is universally recognised in the case of electrolytes must also be conceded when the current is conveyed by a gas, and the idea is gaining ground that even in solid conductors the current consists of positive and negative electrons moving with different velocities. It is the object of the paper to calculate the additional terms which become necessary for the evaluation of self-induction, and to discuss the possible cases in which the corrections may effect experimental results. The mathematical investigation shows that it is necessary to add a correcting term containing a quantity which may conveniently be called electric inertia. The author has calculated the numerical value of this quantity in the case of a solid conductor, and finds it to be about 2×10^{-12} C.G.S. units. It is of the dimensions of a surface. The experiments of Hertz have proved that if electric inertia exists, it must be less than 18×10^{-8}. In the case of liquids and gases, the electric inertia of the moving ions becomes much more important, and the calculation of self-induction by the ordinary processes gives erroneous results. The introduction of a term representing inertia alters the general equations of electric motion, and the author has applied his modified theory to Leyden jar discharges, the electrodeless discharges of J. J. Thomson, and the electromagnetic theory of light. In the case of electrodeless discharges in a vacuous globe, it is suggested that the absorption of energy may not only be due to the conductivity of the gas, but also to the inertia which it possesses.—A paper on magnetic precession was then read by the same author. The most delicate method of investigating the influence of electric inertia is based on the electromotive forces introduced by the motion of conductors carrying electric currents. If electricity behaves like a body possessing inertia, the rotation of a body through which currents pass should affect the flow of these currents in the same manner as the earth's rotation affects the direction of currents of air. If the earth's magnetism is due to electric currents, it is interesting to see if the effects of inertia can explain the secular variation. The investigation shows that a magnetic precession of the character of the secular variation would be produced, but that the precession would be very much slower than the variations actually observed. The subject is worked out mathematically, dealing first with the case of currents in a spherical shell, and then extending the result to the case of a solid sphere. The calculated period of a cycle comes out as 7×10^{14} years. If the currents are confined to a thin slice of the earth, the time would be reduced to about 14×10^{6} years. To produce the actual period of the secular change, the current sheet would have to be of molecular dimensions. This suggests the possibility of the phenomenon of secular variation being rather of a molecular than a molar character. Prof. Rücker congratulated the author upon his attempt to solve the problem of terrestrial magnetism, and expressed the hope that further calculation would throw more light upon this difficult subject. Mr. Blakesley asked if the time of the secular variation would be altered if the interior of the earth were liquid or solid. The chairman observed that the precession was rapid in the case of a thin layer of gas, and mentioned J. J. Thomson's notion that the electrons were thrown off by centrifugal force and formed a molecular layer. Hertz, in his experiments on electricity, had looked for material inertia besides electromagnetic inertia. In the present theory the distinction disappears, and there is only one inertia, and that electromagnetic. Prof. Ayrton said if the two forms of inertia were electromagnetic, he would like to know why, in detecting the second form, it was necessary to associate it with an absorption of energy, as in the case of an electrodeless discharge. In the case of ordinary self-induction there is no absorption of energy, and if there is absorption in the second form, and if they are both electromagnetic, he would like to know the difference between the two. Prof. Schuster, replying to Mr. Blakesley, said that if the interior of the earth were treated as liquid, the period of the cycle would be about one hundred times less. In reply to Prof. Ayrton, he said he had only cited one experiment to show that a phenomenon, explained by the gas being a good conductor, could also be explained by its electric inertia. It was impossible to say in general whether self-induction caused an absorption of energy or not.—Prof. A. W. Rücker read a paper on the magnetic field produced by electric tramways. Taking the case of a tramway in which the current flows along a trolley wire from the power-house, and returns partly through the rails and partly as earth currents, the author has shown that the vertical disturbing force at any point is due to the currents in the feeders and rails, and that the earth currents affect the horizontal force only. Experiment shows that it is chiefly the vertical force instruments which are affected by the establishment of an electric railway, and since this disturbance is due to the wires and rails it is impossible for an observatory to be protected by rivers or other natural features of the district. A preliminary investigation is based on the assumption that the trolley wires and rails are insulated conductors, and that a fraction of the whole current returns along the rails to the generator. The effect of the railway at a distant point is due to the difference of the current in the trolley wire and the hypothetical uniform rail current, the effect of which at the point considered is equivalent to the actual rail current, which varies from point to point. It is thus shown that the disturbance increases with the length of the tramway, and for a tramway of given length the disturbance is a maximum at points on a line perpendicular to and bisecting it. Experiments made at Stockton on the magnitude of the disturbing force gave, with the vertical force instrument, a leakage of 16·3 per cent., and with the horizontal force instrument a leakage of 15·9 per cent., a fairly close agreement. The assumption that the terminals of the line are above and below the average potential of the earth by the same amount respectively, and that the leakage at any point is proportional to the potential difference between the rail and the earth, leads to the ordinary theory of a Fourier bar. This more accurate assumption has been developed and applied to the results obtained at Stockton. The leakage, as calculated from the amperes and volts, comes out as 20 per cent. The calculation of the disturbing vertical force gives $10{\cdot}5 \times 10^{-5}$ C.G S. units, which is in fair agreement with the value 7×10^{-5} actually observed. In conclusion, it is pointed out that for practical purposes it is sufficient to deal with the average return current through the rails, the formulæ for which are quite simple.—Dr. R. T. Glazebrook read some notes on the practical application of the theory of magnetic disturbances by earth currents. In this paper the author has thrown the extended formula obtained by Prof. Rücker in the previous paper into a workable form, and has tabulated numbers which show at what distances the disturbances are negligible for tramways of different lengths.—Prof. R. Threlfall exhibited a quartz-thread gravity balance. Prof. Threlfall gave a short description of this instrument, which has been described in full elsewhere. He drew attention particularly to its accuracy and portability. Mr. Simpson asked how far the fibre had been calibrated, and

if the instrument would be trustworthy at the freezing-point of mercury. Dr. Glazebrook asked how far the instrument was suitable for Antarctic expedition work. He drew attention to the difficulty of calibrating a new fibre should one get broken in the field. Mr. Appleyard suggested the use of a bath kept at constant temperature with a thermostat. Prof. S. P. Thompson suggested a special meeting to discuss the physics of the Antarctic expedition. Prof. Threlfall said that there was no difficulty in measuring the relation between temperature and coefficient of stiffness down to very low temperatures. A more difficult matter is the coefficient of temperature of the instrument. Shrinkage of the instrument as a whole affects both the fibre and the spring which supports it. The difficulty of a broken fibre in the field can be got over by taking two or three instruments. Working with a thermostat is useful in a laboratory, but decreases the portability in exploration work.—Mr. Watson then exhibited a set of half-seconds pendulums. In these pendulums special attention is paid to the stability of the support. The pendulums are covered by a hood, from which the air can be exhausted so that the logarithmic decrement is diminished. The motion of the pendulums is shown by rays of light reflected from right-angled prisms attached to them, and the period of oscillation is determined by the method of coincidences. For this purpose an accurate astronomical clock is used, and observations are made continuously between two time signals. An accuracy of one part in a million is attainable. In reply to Prof. Threlfall, Mr. Watson said that the knife-edges were on the pendulums, and not on the supports.—The Society then adjourned until January 25, 1901.

CAMBRIDGE.

Philosophical Society, October 29.—The President, Prof. A. Macalister, in the chair.—On the structure and classification of the cheilostomatous polyzoa, by Dr. Harmer. This communication dealt principally with the "compensation-sac," a name given by Jullien to a delicate vesicle lying beneath the front wall of the zooecia of many cheilostomes which have a rigid, calcareous body-wall. This cavity, described by Busk in 1884, and with more accuracy by Jullien four years later, has been looked for in vain or altogether ignored by the majority of recent observers. The compensation-sac is in reality an important organ in lepralioid polyzoa, and Jullien's account of its relations is confirmed.—Observations on the minute structure of the surface ice of glaciers, by Mr. Skinner. By pouring plaster of Paris on the ice surface a permanent cast can be obtained, from which it appears that the porosity of the white superficial layer of a glacier arises from two different causes. The first cause is the melting at the interfaces of the crystalline granules, and the second lies in the formation of small pits by the heat absorbed and radiated from small particles of dust. The two classes of holes are very distinct. Those of the first kind are straight furrows joined to form rough hexagons, and those of the second have a cylindrical or ellipsoidal shape. These pits may occur anywhere on the exposed surface of the crystal, and are like in shape to the larger pits formed by small stones and gravel on the glacier surface. Some other casts have been taken of the surface of the ice formed in ice caverns (glacières naturelles); these show only the melting at the interfaces and no pits. In the glacières the melting takes place very slowly and is due almost solely to the contact of air only slightly warmer than the melting-point.

November 12.—Prof. Macalister in the chair.—(1) The natives of the Maldives; (2) The atoll of Minikoi, by Mr. J. Stanley Gardiner. The Singhalese and Maldivians appear to be the result of dichotomous branching of a common stem, one division proceeding through the Laccadives to the Maldives, the other travelling to its present home along the west coast of Hindustan. Mr. J. Stanley Gardiner's second paper was taken as read. The atoll of Minikoi is situated on a bank extending down from the west coast of India to the south of the Maldives. The atoll has in the past evidently been raised to a height of at least twenty feet above the sea, before which it consisted of a mere ring-shaped reef awash. The land is now very rapidly being eroded on every side. The lagoon is broadening and deepening, and the reef is markedly growing outwards. The atoll probably grew up as a flat reef on some mound on the sea floor, subsequently attaining its present shape. The numerous deep bands of the Laccadives represent incipient stages in the formation of reefs on such mounds, while the islands and reefs exemplify the changes, which finally produce the perfect atoll.

November 26.—The President, Prof. Macalister, in the chair.—Some experiments on the electrical properties of a mixture of hydrogen and chlorine, when exposed to light, by Prof. J. J. Thomson. A series of experiments were made to see whether there is any production of free ions when a mixture of hydrogen and chlorine is exposed to light. If any such production took place it would cause the electric conductivity of the mixed gases to increase when exposed to light. This was tested by placing a small gold-leaf electroscope inside the mixed gas; the rate of escape of electricity was found not to be affected by exposure to light, either in the stage just after the incidence of the light when the mixture expands, or in the subsequent stages when the hydrogen and chlorine are combining. The problem was then attacked from a different side and free ions produced in the mixture by the aid of Röntgen rays or the radiation from thorium; though large numbers of ions were produced they had no appreciable effect on the rate of combination of the gases.—On the leakage of electricity through dust-free air, by Mr. C. T. R. Wilson.—Elster and Geitel have shown that an electrified body gradually loses its charge when freely exposed in the open air or in a room. Their results are in agreement with previous experiments of Linss. They conclude from their experiments that free ions exist in the atmosphere. The experiments described in this paper prove that ionisation can be detected in a small closed vessel containing dust-free air not exposed to any known ionising agents. To eliminate any uncertainty due to leakage through the insulating supports, the system from which the leakage was measured was fixed by means of a small bead of sulphur to a conducting rod passing through the wall of the vessel and kept at a constant potential equal to the initial potential of the leaking system. To reduce the capacity of the latter to the smallest possible amount, the whole system from which the leakage was measured was reduced to a small brass strip with a narrow gold-leaf attached, the deflections of which, read by means of a microscope, served to measure the potential. With a capacity of ·73 centim. there is a nearly constant fall of potential in a vessel containing 163 c.c. of air at atmospheric pressure, amounting to 3 volts per hour, the initial voltage being 220. The rate of leak is the same in filtered air whether the apparatus be filled and used in the laboratory (where contamination with radio-active substances might be formed) or in the country. The leakage takes place in the dark at the same rate as in diffuse daylight. The rate of leak is the same for positive as for negative charges. The quantity lost per second is the same when the initial potential is 120 volts as when it is 210 volts. Such voltages produce the "saturation" current and the rate of leak may therefore be used to measure the ionisation. The rate of leak is to a first approximation proportional to the pressure; at a pressure of 43 millims. the leakage is about one-fourteenth of that at atmospheric pressure. If we take the value found by Prof. J. J. Thomson for the charge carried by each ion, $6{\cdot}5 \times 10^{-10}$ E.U., we can take the experiments as indicating that 20 ions of either sign are produced per second in each c.c. of air at atmospheric pressure.—On a solar calorimeter used in Egypt at the total solar eclipse of 1882, by Mr. J. Y. Buchanan. By means of this instrument, which consists of a modified form of a Liebig's condenser mounted equatorially, the solar radiation collected is condensed 48-fold. Observations made with it show that, taking the radius of the earth's orbit to be 212 times the radius of the sun, the radiation of one sq. metre of the sun's surface is spread over 45,000 sq. metres of the earth's surface, whence the sun must radiate energy at the rate of at least 37,300 horse-power per sq. metre of its surface.—Some theorems in regard to matrices, by Mr. T. J. I'A. Bromwich.—On the rational space curve of the fourth order, by Mr. J. H. Grace.—On *Trifolium pratense*, var. *parviflorum*, by Mr. I. H. Burkill.—The writer has been able to examine plants of this so-called variety from Britain and various parts of the Continent, and to show that it is an abnormality in which the carpels are slightly foliaceous, the corolla crumpled, and with a few secondary modifications in other organs.

MANCHESTER.

Literary and Philosophical Society, December 11.—Prof. Osborne Reynolds, F.R.S., Vice-President, in the chair.—On the thermodynamical properties of superheated steam and the dryness of saturated steam, by J. H. Grindley. The paper contained a review of experiments with steam made by various observers. Some calculations were given which showed the

fallacy of accepting Regnault's linear law for the total heat and latent heats of evaporation of steam as a basis from which to determine the specific heats and other properties in superheated steam. Useful expressions for the products of the cooling effects and specific heat at constant pressure in steam were given, which would be of use for purposes of comparison with actual experiment. Two alternatives were offered in the paper for the true facts in saturated steam—either Regnault's results on the latent heats of steam can no longer be accepted, or the data deduced from experiments in the superheated condition must be rejected, as they cannot be made to agree.—On a new species of *Sepia* and on other shells collected by Dr. R. Koettlitz in Somaliland, by W. E. Hoyle and R. Standen. The new species of *Sepia* (*S. koettlitzi*) was collected at Zeila, nearly opposite Aden. It is most closely allied to *S. singalensis*, Goodrich, from which it differs in having the chitinous margin on the dorsal surface much narrower, and in the inner cone being flattened and (if anything) rather concave and not convex.

PARIS.

Academy of Sciences, December 10.—M. Maurice Lévy in the chair.—M. Painlevé was elected a member in the section of geometry in the place of the late M. Darboux.—Examination of the habits of bees from the double point of view of mathematics and experimental physiology, by M. Abraham Netter. It has been usually held by entomologists that four of the habits of bees are intentional. The author contests this view, and attempts to show that all the movements of bees, without exception, are of the nature of reflexes, the bees being really small living machines working entirely automatically.—Observations of the Leonids and Bielids made at Athens, by M. D. Eginitis. The observations were much interfered with by the weather. On the 14th November only six meteors were seen, on the 15th thirty-six, on the 16th fifteen only. On November 23 and 24 only thirty-three Bielids were seen, mostly of the fifth and sixth magnitude.—Observations of the sun made at the Observatory of Lyons with the Brunner equatorial during the third quarter of 1900, by M. J. Guillaume. The results of the observations are summarised in three tables showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude respectively.—Observations of the Leonids made at Rome on November 14 and 15, by M. Rodriguez. Since no observations of the Leonids were reported by M. Janssen, an account is given of the meteors seen at the Vatican Observatory. Details of 107 Leonids are given, for 17 of which the direction during the time of observation was ascertained.—On limited and integrable functions, by M. Léopold Tejér.—On Neumann's method of the arithmetic mean, by M. W. Stekloff.—On the molecular specific heat of gaseous dissociable compounds, by M. Ponsot. Under constant volume or constant pressure the molecular specific heat of a gaseous compound at infinite dilution is lower than that of the mixture of its elements obtained by dissociation.—On the concentration at the electrodes in a solution, with special reference to the liberation of hydrogen by electrolysis of a mixture of copper sulphate and sulphuric acid, by M. H. J. S. Sand. A formula is developed from theoretical considerations for the concentration of a solution of a single salt round the electrodes after passing a current for a given time. In the case of a mixture the formula gives two limiting values between which the experimental values must lie, and the results of electrolysis of solutions of copper sulphate and sulphuric acid in all cases lie between these extreme values.—On the spectra of samarium and gadolinum, by M. Eug. Demarçay. A discussion of the results obtained on these spectra by M. Exner. The wave-lengths are given for the substance regarded by the author as the purest samarium hitherto obtained.—Action of steam and mixtures of hydrogen and steam upon molybdenum and its oxides, by M. Marcel Guichard. Hydrogen completely reduces the oxides of molybdenum to the metal at a temperature below 600° C. Steam, on the other hand, does not commence to oxidise the metal until a temperature of nearly 700° C. is reached. Oxidation of molybdenum either in steam or in mixtures of hydrogen and steam never gives rise to oxides other than MoO_2 and MoO_3.—Remarks on the note of M. Lemoult entitled "Relations between the chemical constitution of the triphenylmethane dyestuffs and the absorption spectra of their aqueous solutions," by M. Charles Carmichel.—On the primitive form of a crystallised body, by M. Fréd. Wallerant.—Quinone, the active principle of the venom of *Iulus terrestris*, by MM. Béhal and Phisalix. It is shown that the active principle of the poison of *Iulus terrestris* contains a quinone, most probably ordinary quinone.—The venom of the *Scolopendra*, by M. S. Jourdain.—On the osmotic pressure of the blood and internal liquids in the cartilaginous fishes, by M. E. Rodier.—Some results of the Belgian Antarctic expedition, by M. L. Kœhler.—On the endogenous formation of the fungus isolated in cancerous tumours, by M. M. Bra.

DIARY OF SOCIETIES.

THURSDAY, DECEMBER 20.

LINNEAN SOCIETY, at 8.—On the Structure and Habits of the *Ammocharidas*: Arnold T. Watson.—The Flora of Vavau, one of the Tonga Islands: J. H. Burkill.—Warning Colours in Insects: Prof. E. B. Poulton, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Lecture on the Electrical Engineers (R.E.) in South Africa: Lieut.-Colonel Crompton.

CHEMICAL SOCIETY, at 8.—On the Union of Hydrogen and Chlorine: J. W. Mellor.

THURSDAY, DECEMBER 27, 1900.

A CONTRIBUTION TO LAMARCKIAN EVOLUTION.

Sexual Dimorphism in the Animal Kingdom; a Theory of the Evolution of Secondary Sexual Characters. By J. T. Cunningham, M.A. Pp. xi + 317; with 32 illustrations. (London: Adam and Charles Black, 1900.)

HOWEVER much readers of this work may dissent from the views of the author, there can be no doubt that the volume is worthy of the most careful perusal. For the first time since the publication of Darwin's theory of sexual selection we have been provided with a bold and intelligible attempt at explaining secondary sexual characters on Lamarckian principles, and although many of us may arrive at the conclusion that Mr. Cunningham has not succeeded in establishing his case, it will be generally admitted that he has discussed the problem, on the whole, in a more or less scientific spirit, and has supported his arguments by a body of well-considered and, in many cases, original observations, which make his book exceptionally valuable as a storehouse of facts.

The author, as is well known, belongs to that school of anti-Darwinian evolutionists which accepts the broad doctrine of descent with modification, but which denies the sufficiency of natural selection as the cause of species formation. In the introduction he re-states some of the chief difficulties and objections which have been urged, over and over again, by the opponents of Darwinism. An analysis of these objections, as set forth by Mr. Cunningham, will show that they resolve themselves mainly into the inutility of incipient stages, the dictum of Romanes that natural selection is a theory of the origin of adaptations, the inutility of specific characters, the failure of natural selection to account for the origin of variation and so forth. Students of evolution are so familiar with these much-discussed topics that we may be excused from dealing with them again in detail. It is ancient history that Darwin admitted "use and disuse" and the "direct action of external conditions" as factors of some value in the production of species. But he assigned a subordinate function to these agencies, and it is quite unfair to Darwin's position to state, as Mr. Cunningham does (p. 12), that "if once we admit this, selection becomes a secondary and subordinate character."

What concerns us most here, however, is not so much the destructive part of the present work, because the author, in brilliant contrast to many critics belonging to his school, has not contented himself with mere cavil or with the watering-down process which is rife among certain sections of naturalists who regard with horror any attempt at dealing with the species problem by scientific method. Mr. Cunningham has formulated his own views, and has applied them to the particular, and, we may add, absorbingly interesting, class of phenomena presented by animals with dissimilar sexes. These views are, as the author will admit, purely Lamarckian—in fact we might say grossly mechanical, since the secondary sexual characters are regarded as the direct result of mechanical irritation or stimulation (p. 37). It is needless to point out that this view is absolutely at variance with that held by selectionists. It is a doctrine which has been broached of late years to account for floral structures, and which, if we are not mistaken, has received but little favour from botanists.

In defining Mr. Cunningham's position as a Lamarckian, it is necessary to point out, in order that full consideration may be given to his views, that he has introduced a certain modification into that doctrine which he claims—and we think rightly—to be original. Lamarckism, of course, carries with it the admission that acquired characters are hereditary, and the author's attitude towards this question will be considered subsequently. But whereas the original, or proto-Lamarckian, or his modern successor, the neo-Lamarckian, never appears to have troubled himself very much about the precise period in the life of the individual at which the "acquired" characters were produced, Mr. Cunningham has laid it down, as the essential part of his amendment, that these characters only become developed (by heredity) at "that period of life and in that class of individuals in which they were originally acquired" (p. 37). He further postulates that, in order to produce such hereditary acquired characters, the stimulations must "be regularly recurrent," and their transmitted effect is then only developed "in association with the physiological conditions under which they were originally produced" (p. 41). In other words, he re-states Darwin's "inheritance at corresponding periods of life" and "inheritance as limited by sex" from the Lamarckian platform, and imposes a new restriction in the way of "physiological conditions" which are nowhere defined throughout the work excepting in the case of secondary sexual characters, where the supposed conditions are vaguely associated with the change of constitution accompanying sexual maturity.

From these considerations it follows that the external stimulus or irritation which (admittedly) can modify a part or organ of an individual during its lifetime, is only capable of producing modifications of specific rank when applied continuously, throughout many generations, at some particular, and at present undetermined, state of physiological activity. Supposing we admit, for the moment, that the author's position is sound for the only case in which such special physiological conditions are hinted at, viz., the period of puberty, then it follows that those mutilations which have been carried out through successive generations in many tribes of savages at the precisely critical period required by the hypothesis might, at any rate, be expected to show now and again a tendency to appear spontaneously in the offspring at that period. The evidence on this point is certainly against the author, and the case for Lamarckism in its amended form receives no more support by virtue of Mr. Cunningham's amendment than did the original Lamarckism from the consideration of such classes of facts. It is, perhaps, not going too far to say that the author's position is less tenable by virtue of his own restriction than that of the older Lamarckians, because the whole explanation of sexual dimorphism, from Mr. Cunningham's standpoint, is made to depend upon the action of external stimuli applied at the period of breeding, *i.e.* at sexual maturity.

It has already been stated that the author repeats, and therefore presumably gives weight to, the stock objection against Darwinism that that doctrine does not account for the *origin* of the variations which selection has to deal with (p. 30). True; but the writer of this notice is not aware that the selectionists have ever pretended that it did, or that it might be expected to. There have been supplementary hypotheses of variation, and there is reason to believe that variability or instability of form, if of advantage to a species subject to rapid changes of environment, might be seized upon and perpetuated by selection like any other character, structural or physiological. But this has nothing to do with the origin of variation as the result of physiological processes. On the other hand, if the theory of natural selection is considered to break down because it fails to account for the origin of variations (which at any rate are facts) what value can be assigned to a theory which *assumes* a special plasticity of the organism under particular "physiological conditions" at a certain period of its life without any adequate proof that such plasticity does exist, and which further *assumes* that external stimuli, acting upon the individual at that period, produce hereditary modifications of structure?

I hope I am not misrepresenting the author's views in pointing out how much in the way of assumption exists in them. It will, no doubt, be said by Mr. Cunningham that his method is logically sound and scientifically correct. Having come to the conclusion that selection is inadequate to account for the facts of sexual dimorphism, he has a perfect right to ask naturalists to examine the evidence which he considers to weigh in favour of his alternative explanation. He says (p. 42):—

"I maintain . . . that theories of selection being found on application to the facts to be insufficient for their explanation, and the theory of the inheritance of acquired characters being found to harmonise with the facts, we are logically bound to believe that such inheritance does take place, at any rate until some other explanation can be found. I do not concern myself with the question how such inheritance can be produced, *it is a fact that the modifications are hereditary, and my object is to produce inductive evidence that they were determined by special stimulations.*" (Italics the author's.)

The author's position towards the question of the inheritance of acquired characters may be paraphrased thus:—Secondary sexual characters appear to be, on critical examination, the result of direct mechanical action upon the individual; therefore we must believe that these characters have been so produced. The non-transmissibility of acquired characters is not an established truth, but only a belief (p. 15); therefore, in view of the foregoing conclusion, we must believe that acquired characters are transmitted.

In answer to this we can only repeat the statement so frequently made in reply to Lamarckian arguments:—All the evidence hitherto adduced in favour of the view that acquired characters are hereditary is either negative or ambiguous, and in cases where, on such hypothesis, the evidence might fairly be expected to be positive, it is also negative or ambiguous. The probabilities are therefore antecedently against Mr. Cunningham's explanation of secondary sexual characters, and we are justified in asking that his proofs shall be very cogent and convincing before we abandon a theory so probable *à priori* as Darwin's sexual selection in favour of a theory which is based on unproved principles. If the non-transmissibility of acquired characters is not an established truth neither is the opposite view, and the author—outside the domain of sexual dimorphism—adduces no new evidence in favour of this view. He says explicitly (p. 37) that he does not propose to prove that acquired characters are inherited, but a few paragraphs further on he lays down a statement of his own opinion which is tantamount to a declaration that such characters are inherited. It may be well, also, before attempting to deal with the detailed statements contained in the seven chapters following the introduction, to point out once again that the obvious adaptation of the parts of an animal to the life habits is no proof that the structural modifications have been produced by the habits. It may appear, *primâ facie*, that the structure is caused by habit, but this is no proof that it is so caused. The same result can be brought about by selection, and it is quite unnecessary to insist here that this is the essence of the Darwinian theory. But Mr. Cunningham is quite consistently Lamarckian in his inversion of the Darwinian position. Throughout this work the reader will meet with statements which remind us of the old Lamarckism—that such and such a structure *is produced by* such and such habit. In one illustration (p. 171) he even goes so far as to demonstrate that by moving a pen-holder coated with sealing-wax to and fro in hot water the softened wax forms a lamina above and below in the plane perpendicular to the plane of the motion, from which he apparently wishes us to believe that the crest of the male crested-newt "is due to the active movements of the male in courting the female in the breeding season"!

The special evidence which the author brings forward in support of his views is contained in some two hundred and sixty pages, divided into seven chapters, each dealing with the secondary sexual characters of some class or classes of the animal kingdom, from mammals downwards. It is impossible to deal with the various cases in detail, but a few typical examples may be selected in order to illustrate the position of those who, like Mr. Cunningham, regard habit as the cause of structure. The discussion of the sexual differences in man, in the first chapter, will be found particularly instructive. The hair on the face of the male is supposed to be "due to the stimulation of the growth of the hair by teeth or hands in the combats of mature males" (p. 49). That is to say that man's ancestors, by pulling each other by the hair of the face during their struggles for the female, developed a beard and moustache. But if mechanical irritation or stimulation of the hair follicles is the cause of increased growth of hair, why should the hairless condition of man's body, as compared with that of the apes, be attributed to the wearing of clothes (p. 52); the baldness of civilised races to the wearing of hats (p. 53), and the greater length of hair in woman to the wearing of lighter head-gear (p. 54)? Surely the hair follicles of a clothed animal are subject to more pressures and stimulations than in the naked animal? In a similar way,

the author discusses, in this chapter, the origin of antlers, horns and tusks, which, being used for fighting, have, according to his views, been developed by pushes and stimulating shocks. The cheek prominences of the male mandrill are considered to have been produced by a similar process, and their furrows and colour are regarded as "inherited swellings and scars" (p. 58). The case for Lamarckism, as based on a study of antlers, is worked out at great length also in this chapter, this being a subject to which Mr. Cunningham has devoted special attention. The tusk-like development of the upper canines of the male musk deer is explained in these words:

"The enlargement of a tooth is as natural a consequence of excessive use as is that of an antler, the pressure stimulating the papilla or pulp from which the tooth is developed" (p. 96).

The author adds, however, that the evolution of the musk gland of the male "is more difficult to explain."

Those who are familiar with Darwin's weighty body of evidence in favour of sexual selection derived from his studies of the secondary sexual characters of birds will turn with interest to the discussion of this subject in the second chapter of the present work. The excessive development of male plumage is, according to the author, the result of use—*i.e.* to erection by muscular action during display. But the most striking sexual differences among birds are not only due to development of plumage, but also to colour and pattern, and just on this point Mr. Cunningham's application of Lamarckism becomes most unsatisfactory:—

"With regard to the coloration and markings of special plumage I have little to say. I regard them as due partly to the same excessive growth as that which increases the size of the feather, partly to the universal regularity and symmetrical repetition of marks, due to the rhythmical nature of growth processes, and partly perhaps to the action of the light from particular surroundings" (p. 109).

From this point of view, it is interesting to see how the author deals with the ocelli of *Polyplectron* (p. 114). Darwin, as is well known, attributed the dull ocelli of the female to partial transference of the male characters. Mr. Cunningham inverts this explanation, and suggests that the present condition of the female represents the original condition of the male. In other words, the ocelli of the male as at present seen are the female ocelli developed and enhanced by "use inheritance." The writer of this notice fails to see wherein this explanation offers any advantage. The duller ocelli of the female have, on this view, still to be accounted for. What direct action or external stimulus or impact can be conceived which is capable of producing regular patterns? The "action of light from particular surroundings" (even if we admitted such action) could not produce an ocellus, and if the "rhythmical nature of growth processes" is considered a sufficient explanation, this and all similar cases are at once removed from the discussion, and have no more to do with the author's Lamarckism than with the older Darwinism.

The whole treatment of colour and pattern throughout the work leaves no doubt that the author proposes to ring these characters within the domain of his amended amarckism. Among Amphibia, for example, the more vivid colouring of the male *Molge aspera* is attributed to the greater sexual excitement of the male, which causes, "through nervous stimulation, more active production of pigment in the skin" (p. 175). Among fish—a class to which Mr. Cunningham has paid special attention—the same explanation is offered again and again to account for the brighter colours of males. In those exceptional cases where, as in *Solenostoma* (p. 227), the female is the more brilliantly marked and coloured, the author is obliged to reverse the nervous excitement of the sexes. Perhaps the most instructive case dealt with under this division is that of the male dragonet, *Callionymus lyra*, because it is discussed at great length (pp. 199—214), and may be taken as a typical example of the author's treatment of the problem of colour as a secondary sexual character. The habits of the fish have, moreover, been most thoroughly observed and recorded by Mr. Holt at the Plymouth Marine Station. In summing up this case Mr. Cunningham concludes, as before, that the increased sexual excitement of the male at the breeding period causes, through nervous stimulation, an increased deposition of guanine and pigment in the skin.

"That the marked excitement of the male dragonet's brain should cause increased nervous stimulation of the skin is not an extravagant supposition, and it is definitely supported by the fact that the blue bands, if not the yellow, are flashed out in more intense brilliance as the fins are raised in his amatory rushes. When the question is regarded physiologically, instead of merely from the selectionist's point of view, the significance of such reasoning as I have used cannot be ignored."

In this paragraph Mr. Cunningham takes up a position that is very frequently assumed by opponents of the selection theory, and from which the writer of this notice desires to take this opportunity of again expressing his dissent. The fact that the blue bands are flashed out as the fins are raised is surely an optical effect. I can hardly imagine that even the Lamarckian zeal of the author would lead him to desire that his readers should suppose that the "amatory rush" of the male caused an immediate and suddenly increased secretion of guanine! But apart from this, supposing we admit that he has discovered the true physiological explanation of the colour—and that given on p. 211 may be perfectly correct—wherein does this favour the Lamarckian and discredit the Darwinian explanation? It appears to be constantly assumed by anti-Darwinians that because they have found the physiological and histological mechanism of a colour they have thereby disposed of selection. We say that selection is capable of acting upon *all* characters, external and internal—whatever their physiological origin; and, in this particular case, if the male fish were capable at the breeding period of secreting guanine to such an extent and in such an arrangement as to produce a visible blue colour, we should say that there is here a character which is quite as capable of being enhanced and developed by sexual selection as is any other character of biological value to the species by natural selection.

In association with the hypothesis that colour is the result of increased deposition of pigment due to sexual excitement, it may be pertinent here to raise the question why, on Lamarckian principles, the increased secretory

and excretory activity should take the form of colour at all. It can be admitted in a general way that increased nervous stimulus might lead to increased secretion and excretion generally. But there is no evidence of any kind brought forward in support of this—the evidence which Mr. Cunningham asks us to accept in favour of his view centres round *local deposits* either of osseous or horny matter, &c., in the case of mammals, or of pigment. Colour, as such, is meaningless from the Lamarckian standpoint, and we have a right to ask where is the "use" (in the Lamarckian sense) which accounts for the accumulation of such deposits in definite stripes and patterns in one part of a wing or feather. If it be suggested that the definite arrangement is the external expression of an internal law of growth, then the diversity of pattern among allied species remains unexplained; and, if we allow the direct action of light as a cause of pattern, we are invoking an improbable and an unproved principle. It must be presumed that the author considers his experiments on the coloration of the *Pleuronectidae*, to which he refers on p. 41, as a sufficient proof of "the direct effects of stimulations." At any rate this is the only instance specifically mentioned which has any direct bearing on the question of the action of light as a colour-producing stimulus. It appears to the writer, however, that the results which Mr. Cunningham made known in 1896 are open to another interpretation from the point of view of the selection theory, but the discussion of this point would be out of place in the present notice.

If the "nervous excitement" theory of colour is considered sufficient as regards deposition of pigment, the production of colour by purely physical methods, such as striation and lamination, has yet to be faced by the Lamarckian school. This aspect of sexual coloration is very lightly dealt with by Mr. Cunningham, although, in the case more especially of birds and insects, some of the most gorgeous male characters are due to such colours. It is, perhaps, hardly right to attribute unfairness to an author who evidently has done his best to give due consideration to the doctrine which he is opposing, but impartial readers of the present book who happen to be acquainted with the subject at first hand cannot fail to detect the anti-selectionist bias which here and there makes itself manifest in Mr. Cunningham's pages. Nowhere is this more obvious than in the fifth chapter, dealing with the secondary sexual characters of insects. The bias is no doubt unconscious, but when we consider that among butterflies, to which the author devotes the larger part of the chapter, this kind of colouring plays such a very important part, the treatment will be found, to say the least, disappointing by those who wish really to know what the Lamarckians have to say on this subject. The explanation offered is that the colours—pigmentary and physical not being separated—are caused by the direct action of light:

"If we assume that variations in definite directions are excited by external conditions, in this case principally by light of different colours, the facts become intelligible in general," &c. (p. 243).

"By exposure I mean the kind of light to which the surface is exposed, and I believe that in Lepidoptera the coloration has chiefly been determined by the quality of the light" (p. 245).

We do not believe that the author will make many converts to his amended Lamarckism by such explanations as these. When and how does the light act, and how can such action produce pattern? Is the pattern focussed on to the wing by some mysterious agency capable of acting as a lens, or how does the light of different "qualities" (? wave-length) get separated so that each component produces its proper chromatic effect? Upon what organic tissue can light produce such direct photo-chromatic action, and does such action take effect through the skin of the pupa, in which stage the colours, both pigmentary and physical, are formed in the rudimentary wing? It seems to the writer that, instead of the facts being made "intelligible in general" by invoking such strained explanations, they have been rendered hopelessly inexplicable from the Lamarckian standpoint For example, to take his own illustration, does Mr. Cunningham wish us to believe that the hind-wings of *Catocala nupta* have been exposed to red and black light for generations—if so, where is the evidence? Does he seriously believe that the mottled-grey of the fore-wings, which, as he admits, makes them "indistinguishable on surfaces of bark or rock" (p. 246), is better explained by the direct action of the light from such surfaces than by a straightforward admission of natural selection for the purposes of protection? If he does prefer this explanation it must be left for the readers of this review to consider whether any bias is displayed by the author of the work under notice.

In discussing the colours of Lepidoptera, the author begins with those cases in which there is mimicry combined with sexual dimorphism, the females being, generally speaking, the mimetic forms. His object in doing this is to bring into prominence the undisputed fact that in such cases the two sexes have different habits. His contention, of course, is that the habits have produced the differences between the sexes. But if we do not admit this—and selectionists will not accept this doctrine until some much stronger evidence is forthcoming—the whole force of the argument is lost, because the difference in habit is also precisely in harmony with the requirements of the selection theory. What is really wanted to make this argument of any value is the proof that in species which are *not mimetic*, but which are nevertheless sexually dimorphic, there is a sufficiently marked difference between the habits of the sexes to account for the greater brilliancy of the one sex. So far as the writer has observed, there is no marked difference of habit leading to different exposure, for example, between the male and female in species of *Colias*, *Anthocharis*, *Pieris*, *Gonepteryx*, *Hipparchia*, *Satyrus*, *Argynnis Hesperia*, &c. Yet in all these there is in most of the species a marked dissimilarity of sex. To narrow down the issue, why, on Lamarckian principles, should the male orange-tip (*A. cardamines*) have an orange patch on the fore wings, and the female *Colias edusa* a row of orange spots round the black border? Why should the male *Gonepteryx rhamni* be bright yellow and the female greenish-white?

In all cases where direct observation is wanting, or where there is no observable difference of habit between the sexes, the author assumes that there must be some such difference. Of course this is a very easy way

of "explaining" things by Lamarckism or any other hypothesis; but as this method is freely indulged in throughout the book, and since Mr. Cunningham is nothing if not logical, it may be well to examine a little more critically his position in this respect. The kind of assumption to which reference is made is well illustrated, not only by the chapter on insects, where colour is chiefly dealt with, but also in other classes where structures of unknown use are possessed by the males. Thus, among birds, the males of *Chasmorhynchus nudicollis* and other species of the genus are supposed, without evidence from observation, to fight and to

"seize their adversaries by the skin at the base of the beak, the attack being directed to the chin or the forehead, according to the species" (p. 145).

This is put forward as a "probable conjecture," because the male characters require such Lamarckian stimulations to account for their presence. Among chamæleons, the male, *C. Owenii*, has three slender horns which are not known to be used for fighting;

"but the animals are known to be quarrelsome, and it is probable that the appendages are thus used" (p. 166).

In this case the author even allows his logic to go by the board, because he follows up this statement, which is only conjectural, with the remark:

"Here again, therefore, we find that the existence of outgrowths corresponds to the impacts produced by definite actions, both being confined to the male sex."

That is to say, that a function which is conjectured to be probable in one sentence is treated of as an established truth in the following sentence. Examples of this kind might be multiplied, but the foregoing will suffice. Now the point which the writer of this notice wishes to urge is that all the arguments of this class are arguments of analogy only, and the weight which attaches to them is dependent on the antecedent probability of the hypothesis in support of which they are brought forward. Mr. Cunningham has, by implication, admitted the antecedent probability of Lamarckian factors; but if we do not follow him—and no selectionist will—much, if not all, the force of the analogies is lost, and we have a right to demand proof of actual connection between male structures and their use in every case described by the author. It is not to the point, in such cases, to urge that because in one species the male has been seen to use appendages or excrescences for fighting, therefore in other species with similar growths these must be used for the same purpose. The theory of sexual selection allows that male characters of the kind referred to may have been developed for ornament or as weapons of attack or defence, or for both purposes. But Lamarckism must have a definite mechanical cause for each excrescence or appendage, and the failure to discover such cause in any particular case is so fatal to the doctrine that most impartial readers of Mr. Cunningham's work will, on this ground alone, reject his conclusions. In one case (*Turnix taigoor*, p. 118) where the females are known to fight, and where there is no modification of structure corresponding to this habit, the author suggests

"that the pugnacity of the females has but recently arisen in the evolution of the genus, but it may be that the wounds inflicted are not very severe" (p. 120).

Many other points in the volume under consideration are open to criticism, and, in view of the importance of the issues, demand notice. Reverting again to the chapter on mimicry, the author, in rejecting the obviously simple explanation offered by selection for protective purposes, says that

"the theory of specific mimicry involves assumptions that have not been sufficiently realised. It assumes that birds or other enemies of butterflies are as precise in entomological discrimination as the human specialist" (p. 241).

This is hardly a correct statement of the case; the assumptions made by the theories of mimicry (Batesian and Müllerian) have been thoroughly well realised, and a body of evidence, both observational and experimental, has been brought to bear upon these theories, which Mr. Cunningham has either overlooked or chooses to ignore. But his own assumption, which precedes this statement, displays such an astonishing misapprehension of the whole subject that we can only come to the conclusion that the author has not really made himself master of the theory which he is endeavouring to overthrow. Having admitted that mimicking forms may belong to persecuted groups, he still suggests that, after all, the mimics may not owe their safety entirely to deceptive *appearance*, and he then goes on to say:—

"Inedible forms, such as the Heliconidæ, the gooseberry caterpillar and others, are distasteful largely in consequence of the presence of the pigments which make them conspicuous. *Therefore when a mimicking form acquires similar pigments it probably likewise ceases to be palatable to insect eaters*, and would be equally unmolested even if it possessed no particular resemblance to a species of another family" (p. 241. Italics ours.)

It really appears from this as though the author believed that the mimicry extended to similarity of pigment, which is not only contrary to the truth, as established by the researches of Mr. Gowland Hopkins, but is in itself so improbable *à priori* that it is surprising that Mr. Cunningham should have committed himself to the statement.

Considered as a whole, there can be no doubt that this fifth chapter is the least satisfactory in the book. It not only contains misstatements such as the above, but its omissions show that the author has not made himself acquainted with the recent developments in this direction. As the Arachnida are not considered at all, the splendid observations of Mr. and Mrs. Peckham on the courtship of spiders are not discussed. The reference to Poulton's experiments on the influence of the colour of the surroundings on the colour of the larva and pupa, as an illustration of the modifying action of the "quality of the light" (p. 231) upon the colour of the wing of a butterfly, is a false analogy. The statement (p. 248) that "the beauty of a butterfly's wing is equally visible whenever the insect flies" does not convey the whole truth, because in many of the most gaudily coloured males the full splendour of the colour is only seen from the front aspect, *i.e.* facing the insect and looking across the

surface of the wing, the aspect that would be first seen by the female if the male were flying straight towards her. Nowhere is this iridescent colouring better seen, by the way, than in the male *Hypolimnas bolina*, figured by the author on p. 233.

Although there can be no doubt that Mr. Cunningham's plea for Lamarckism and the inheritance of acquired characters is on the whole very ably supported, it will not fail to strike many of his opponents that his anti-selectionist zeal carries him too far in some of his most fundamental arguments. Like many of the recent critics of Darwinism, the author now and again reads into the theory of selection certain deductions of his own, which he then proceeds to demolish without considering whether his deductions are legitimate or not. For example, he considers it an objection to the Darwinian explanation of flying mammals (p. 15) that

"the variations in the condition of the skin in animals that do not fly or take long leaps through the air are not such as to justify the belief that these variations would make any difference in the struggle for existence when long leaps became necessary."

That is to say that other animals besides those that do fly might be expected to show, on occasion, the raw material, so to speak, for potential flight. This is a kind of argument which has constantly been used by anti-Darwinians. Why, because a certain species has been enabled to develop such and such a useful character, have not similar characters been developed in other species to which they might be equally useful? It appears to be again necessary to point out (1) that it is not part of the Darwinian theory to suppose that every species is capable of varying *in every possible direction*; (2) that modification in the direction of flight may not have been possible in the species which "do not take long leaps through the air"; and (3) that such species have, no doubt, survived by the development of some other method of escape or defence which is quite as effective. Arguments of this sort might equally well be urged against the Lamarckians. Why, for instance, do not the flying lemurs, squirrels and foxes, &c., fly as well as bats, seeing that the membranous expansion of skin is constantly being used for gliding through the air? The writer has no desire to press this point against the author of the present work.

Then, again, Mr. Cunningham insists frequently that his (Lamarckian) explanation accounts for unisexual inheritance, while sexual selection does not. I believe that I shall not be singular in declaring my inability to see any force in this argument. Inheritance, as limited by sex, is a fact. Mr. Cunningham says (*e.g.* on p. 252) that this limitation is due to the "stimulations" having been applied to one sex and not to the other. But even if this were the true origin of the male characters there is absolutely nothing in the Lamarckian explanation which accounts for their non-transmission to the female. All characters, whether secondary sexual or not, must on either hypothesis (Lamarckian or Darwinian) originate in an individual, which individual must—it is needless to say in the case of bisexual animals—be either male or female. Why, then, should there ever be any blending of characters at all? According to Darwin's theory, the male characters originate through the selection of spontaneous variations by the females; according to the amended Lamarckism, the male characters are, as it were, hammered out of the male by stimuli applied at the period of sexual maturity. Why should this latter view be supposed to account for the limitation of the male characters to the male, and the former view (Darwin's) to fail? Or, to put the case in another way: Why should characters impressed mechanically upon the male during a particular period of his life be hereditary, and characters arising by spontaneous variation at that period not be hereditary? If the author had contented himself with the acknowledgment that unisexual inheritance required further explanation, both schools of biologists would agree. The selectionists might even have suggested an answer on the lines laid down by Wallace—that the female, being in most cases in greater need of protection and concealment, had had any tendency to inherit the male characters eliminated by natural selection. The author will no doubt reject this explanation; but whether he does so or not, it is manifestly absurd to claim for Lamarckism a fictitious superiority as regards the explanation of unisexual inheritance. The advantage seems to the writer to be distinctly on the side of the Darwinians.

If, as we believe, this latest attempt to reinstate Lamarckian evolution is unsuccessful, its failure is due to the inherent weakness of the doctrine rather than to the treatment which it has received in the present volume. It was an excellent idea on the part of Mr. Cunningham to test this theory by applying it to secondary sexual characters, but it does not appear that the light shed by Lamarckian assumptions is in any way clearer than that offered by the theory of sexual selection. There are, confessedly, difficulties in the way of both theories, but those offered by the Lamarckian doctrine are certainly the more serious. The writer, at any rate, has come to the conclusion that few biologists in this country will accept the mass of material offered in the present volume as "inductive evidence" in favour of the heredity of acquired characters. Most of the cases discussed are equally well explained by the theory of selection—some cases are better explained by this theory. Assumptions and deductions have to be made by the supporters of both theories; those required by the Lamarckians seem to be much the less warrantable. It may be fairly said that if Lamarckism breaks down in its application to such characters as those dealt with, its career as a working hypothesis has ended fatally. It would certainly be interesting to know whether the author limits his Lamarckism to the production of secondary sexual characters, or whether he regards his amended form of the theory applicable to *all* specific characters. Limitation hardly seems possible logically, because any stimulus or impact of any kind whatever must (on this hypothesis) produce its effect if applied at the right stage of physiological activity. The author, if he accepts this wider application, will thus have narrowed down the issue between the two schools of evolutionists to the simple question whether hereditary modifications can be produced by such means. We believe the answer will be in the negative, but if this wider view is not accepted, then Mr. Cunningham must show cause why the modification should be restricted to such characters as those which he has so ably discussed in the volume which has been considered in this notice.

R. MELDOLA.

OPTICAL SCIENCE.

A Treatise on Geometrical Optics. By R. A. Herman, M.A., Fellow of Trinity College, Cambridge. Pp. x + 344. (Cambridge: University Press, 1900.)

IN the preface to a recent book dealing with photographic optics, Prof. S. P. Thompson expressed the view that Sir John Herschel's article, "On Light," in the "Encyclopædia Metropolitana" of 1840 marks the culminating point of English writers on optics. Whether this is still the case or not perhaps need hardly be discussed; it may safely be said that Mr. Herman's book, which contains many novel points, constitutes a marked advance, and brings before English students a quantity of information which was not easily accessible to them before.

At the same time, the book undoubtedly suffers as a treatise on the subject from being a text-book for mathematical students at Cambridge. Mr. Herman has aimed at attracting a wide circle of students. The most elementary proofs of the simplest theorems are given alongside of mathematics which require a considerable training to follow easily. The book would have gained as a treatise if the author had assumed his readers to possess some elementary knowledge of the subject and its simplest formulæ. A Cambridge coach might put it in the hands of a beginner, marking, say, two-thirds as to be omitted at first reading; that two-thirds, with some slight re-arrangement and addition, would make a more interesting book for the more advanced student than the actual volume now under review. Thus the theory of geometrical foci, the methods of constructing a figure to find the image of a small object placed perpendicularly to the axis, of a system of spherical reflecting or refracting surfaces and similar problems could all be put more briefly.

In Chapter ix. (General Theorems) we come to Fermal's theorem; the general theory of geometrical foci is here given, based on this theorem. The author remarks that all the theorems hitherto obtained for small pencils passing directly through a coaxial refracting system might be obtained from the formulæ arrived at; the advanced student would have gained a closer grip of the subject as a whole had this course been taken. The formulæ can be extended to establish the collinear relation between the object space and the image space, and, when once this is done, the existence of the principal and nodal points follows, and the geometrical constructions based on a knowledge of their position are easily generalised. The introductory methods of Drude's recent "Lehrbuch der Optik" seems, in this respect, more suited to a treatise on the subject than those chosen by Mr. Herman, who appears to have been deterred from using them by his wish to make it clear throughout that the method of geometrical foci is only an approximation. But in spite of this the merits of the book are very great. The author, in his introduction, states that it has been one of his aims

"to introduce a new method of determining the properties of a symmetrical optical instrument in which the angle of divergence of a small pencil, rather than any coordinate of its origin, has been adopted as a leading feature."

The method rests on a combination of Cotes' theorem of the apparent distance, and Helmholtz's expression for the linear magnification.

The simplification that results from its use in the case of a symmetrical pencil traversing a coaxial system of lenses is most marked; the lengthy calculation of the continued fraction by means of which the results are arrived at in Gauss's treatment of the subject is entirely avoided. The application of the method to the determination of the axial aberration of such a system is a striking example of its power; this is easily seen by comparing Chapter viii. (Aberration) with the corresponding portion of some earlier text-book.

In the chapter on instruments the discussion of telescopes is very satisfactory. The same can hardly be said for that on microscopes; probably it would be too much to expect an explanation of the complete theory within the limits of space which could be assigned to the subject, but the discussion should have come after the chapters on aberration and achromatism; it would then have been possible to refer to the problem of the manufacture of suitable glasses which Abbé set himself to solve in 1881—this is alluded to in a perfunctory manner in § 123—and to indicate in a general way the outlines of the theory and the methods in which the defects of one lens are corrected by the next.

The problems to be solved in the construction of photographic lenses can, perhaps, hardly be discussed fully without more complete calculations of the aberrations of oblique pencils than is possible in a general treatise; still, space might have been found for a reference to von Seidel's work, and some discussion of the physical meaning of his five equations of condition would have been interesting and valuable even if the reader had been referred to the original papers for a proof of the conditions. In fact, the book would be improved in many places if the account given of modern German work were more complete; in the chapter on achromatism, for example, full details are supplied of the refractive indices and dispersive powers of several specimens of crown and flint glass; details as to Abbé's glasses, which contain salts of boron, phosphorus and barium, together with some note as to the effects produced on the optical properties of the glasses by these salts, might well have been added. The book is so notable and valuable an addition to the literature of a rather neglected subject, that it is a pity it is not more complete in these respects. It is printed by the Pitt Press in its usual admirable style; the collection of examples, both worked and unworked, is specially full, and will be found very useful to the student. As a text-book it is a marked advance on anything yet published in England.

OUR BOOK SHELF.

By Land and Sky. By the Rev. John M. Bacon, M.A., F.R.A.S. Pp. viii+275. (London: Isbister and Co, Ltd., 1900.)

MEMBERS of the British Association who were at the Dover meeting may find in this book, among other things, some account of the intentions and the performance of the balloon that occupied for so long a time the grounds of Dover College.

Whether the book was intended to be the British counterpart of its ponderous contemporary in three volumes recently issued by the Aëronautical Society of Berlin does not appear from anything that is written therein. It deals with the same large subject—scientific balloon voyages—but it is not a work of reference. It could hardly be so, for it has no index, and the table of contents serves more to stimulate curiosity with attractive head-lines, as "Marooned" and "How I bombarded London," than to guide the reader to any scientific results. It is not even effective as an indication of what is to be found in the chapters, for what the author has to say, for example, on the natural history of gorse and bracken is to be found in the chapter headed "fog signals."

The leading motive of the book, in so far as it is not autobiographical, is the application of balloon observations to certain problems connected with the transmission of sound, and this leads to spending midnight hours on a tower of St. Paul's, to a long stay at the Maplin Lighthouse, and other eerie expeditions, but to no effective scientific results except the destruction of the author's belief in aërial echoes.

The book has, in fact, all the discursiveness of the *dilettante*. Its scientific investigations lack the definiteness which quantitative measurements give. It describes in one chapter how a certain echo always arrived behind time, but it does not say how the time-table was drawn up. Still, it deals with a number of interesting balloon excursions and the adventures that they afforded; the style is racy in its way, the illustrations are good, and the printer has given effective assistance. The reader will at least learn that ballooning is still in the adventurous stage, and, if he thinks about it, he will conclude that some scientific methods are better than others.

Der Aufbau der Menschlichen Seele; Eine Psychologische Skizze. Von Dr. H. Kroell. Pp. v+392. (Leipzig: Engelmann, 1900.)

DR. KROELL'S work might be judged from two very different points of view. As a popular and generally intelligible account of the present state of our knowledge as to the localisation of function in the brain and the stages of cerebral development, some of his chapters may be highly commended for their clearness and accuracy. As a "psychological sketch" of human life and thought, written with the avowed object of establishing the materialist position, the book is an unqualified failure. Dr. Kroell brings out materialism in his results simply because he has put it into his premisses. He is content to assume the first principles of mechanical physics, not, as a real physicist might do, as working hypothesis, but as unquestionable and ultimate truth. Moreover, he states even those principles in an unsatisfactory way. The difficulties which beset the problem of the relation of matter and energy are ignored by the convenient device of asserting that each is one aspect of a double reality which the author calls "Kraft-stoff"; unfortunately he omits to tell us how "Kraft-stoff" is to be measured. He assumes, with equal recklessness, that all energy is kinetic (p. 28) and (pp. 30, 31) that the phenomena of life *must* be capable of being adequately described in terms of rotatory motion. Dr. Kroell's psychology is of the same type. He can see no difference in principle between the photo-chemical changes produced on the retina by a light-stimulus and the transformation of molecular motion into consciousness which, on his theory, take place in the cortex. The "picture in the brain" is a reality of the same order as the "picture on the retina." That neither "picture," as distinct from its physical conditions, exists except for the eye of an observer does not occur to him. A sensation (p. 70) is actually said to be a cerebral process which has become "conscious of itself," though, of course, our own cerebral processes are in point of fact precisely that of which we are *never* directly conscious. The sensation as a mental state is confused with its own cortical concomitants and baptised by the name of "picture in the cortex" (p. 98); and the unmeaning question has then to be discussed how it comes about that the "picture in the cortex" is "referred away outside" to the periphery of the body or to a spot in the external world. The questions of animal psychology, which all serious students of the subject know to require the most cautious handling, are settled by Dr. Kroell in the same spirit of jaunty confidence. For instance (p. 125), the higher animals have memory-images. This is roundly affirmed without evidence, apparently in utter ignorance of the actual experimental work which has been done in the study of the animal mind and the much more guarded conclusions to which that work points. Animals (*ib.*) have "concepts," though no word is said as to the evidence which has satisfied the author upon this thorny and debated subject. These are but a few specimens of the confusions of thought and reckless assertions with which the book abounds; they should be enough, however, to indicate the worth of an argument for materialism founded on such premisses. Psychologists have no right to quarrel with physiologists and medical men for not being themselves psychologists; they surely have a right to expect that psychology, as much as any other science, should be protected against the dogmatism of outsiders who disdain to make themselves acquainted with its problems and methods. No knowledge of physiology can give its possessor the right to dogmatise *à priori* in physics and in psychology.

A. E. TAYLOR.

Shakespeare's Greenwood. By George Morley. Pp. xx + 289. Illustrated. 16mo. (London: D. Nutt, 1900.)

OF this daintily turned out volume, some portions have already seen the light in an abbreviated form in the columns of *Knowledge*, *Country Life* and the *Art Journal*, but the greater part is new. And the author, who is already known to the public by other descriptions of Warwickshire scenery, claims for his present effort the position of being the only work that deals with the survival of old-time feeling and custom in Shakespeare's country.

Naturally the work is in the main interesting to the antiquarian, the philologist and the student of folk-lore rather than to the zoologist; but there is a chapter on birds from which the ornithologist may possibly glean a few facts in regard to habits and local nomenclature. As an example, we may refer to the incidental statement on p. 194 to the effect that the name "landrail" (like corncrake) is derived from the cry of the bird to which it is applied. It may be that this derivation, although previously unknown to ourselves, is familiar to ornithologists, but we have failed to find mention of it in three standard works on British birds.

The popular superstitions connected with the redbreast and the wren are sympathetically referred to on pp. 153 and 154. And an old-time belief connected with egg-shells is detailed on p. 173. It appears that in Warwickshire it is the custom to scrupulously preserve these, although, at the pain of ill-luck, on no account should they be kept in the house. "But if by any mischance," says our author, "some person, unacquainted with the folk-lore of the subject, should burn the egg-shells, then, in the rustic belief, the hens will cease laying. Where this faith is the strongest is in the isolated homesteads on the waste or by the side of a wood, and there the utmost care is taken to prevent any single egg-shell being thrown into the fire, so that the fecundity of the hens may be stayed." It would be very curious to discover the origin of this and many other strange superstitions referred to by Mr. Morley.

To those of our readers interested in folk-lore, as well as to all Shakespearian students, the elegant little work before us may be heartily commended.

R. L.

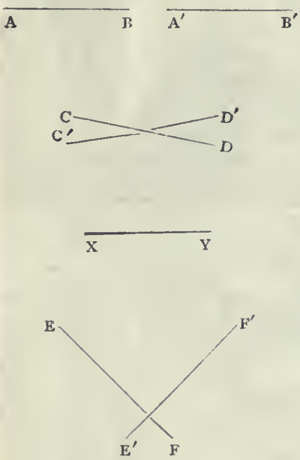
LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Relative Motion of the Earth and the Ether.

IN recent issues of NATURE and the *Philosophical Magazine*, Profs. Larmor and Fitzgerald and Lord Kelvin have expressed themselves as if satisfied that the negative result of the celebrated Michelson and Morley experiment as to a relative motion of earth and ether is genuinely decisive, and as if the only present escape from the dilemma between this experiment and the bulk of the evidence which necessitates a relative motion of earth and ether is to be found in a possible change of the dimensions of bodies caused by changes in their motion through ether.

I should like to point out that a much less heroic alternative is offered in an article of mine on relative motion of earth and ether in the *Phil. Mag.*, January, 1898. It is there shown that the optical apparatus used by Michelson and Morley was probably in a less sensitive condition than was assumed, and, therefore, failed to determine the very minute distance which was the subject of measurement in their experiment. The argument of my paper can be illustrated by the following considerations. Let AB be a source of light, and let A′B′ be a duplicate of it, for example AB and A′B′ may be the two images in Fresnel's production of interference fringes by a biprism. The distance apart of the fringes at any place is inversely proportional to the distance between AB and A′B′.



But if, instead of a duplication such as AB and A′B′, we have one such as CD and C′D′, then an eye at XY can see fringes whose width depends on the angle at which CD is inclined to C′D′. These are two simple limiting cases with correspondingly simple laws. Michelson and Morley assume that their apparatus gives them the case of CD and C′D′, but there is nothing in the arrangement of their apparatus to ensure that the case shall not be like that of EF and E′F′, where the two images have suffered both the angular displacement of CD and C′D′, and the lateral displacement of AB and A′B′. The law of the width of the fringes due to EF and E′F′ must be such as will include the laws of AB and A′B′, and of CD and C′D′ as limiting cases. I hold, therefore, that the Michelson and Morley experiment is vitiated by the assumption that their apparatus gave them the full sensitiveness of the CDC′D′ position, whereas it really gave the unknown smaller sensitiveness of the EFE′F′ position.

They found that the displacement which they measured was probably less than a fortieth of what might be expected as due to the earth's orbital motion. I maintain that a possible alternative to this conclusion is that the sensitiveness of their apparatus was probably less than a fortieth of what they assumed it to be.

On account of the great importance of the subject it is very desirable that this experiment should be repeated with a definite experimental measurement of the actual sensitiveness of the apparatus employed. It would be indeed a great help in astronomy if we could have Michelson and Morley apparatus of known adequate sensitiveness in our observatories furnishing continuous record of the earth's motion relative to the ether, from which we could calculate the drift of the solar system, and ultimately express all stellar movements with reference to the ether. WILLIAM SUTHERLAND.

Melbourne, November 6.

Virgil as a Physicist.

IT seems to have escaped observation that, just as Homer appears to have known of, and even given names to, the two attendants or satellites of Mars, so Virgil is the earliest to mention that now familiar substance, "liquid air." In proof of this I may cite the following passages:—

(*a*) Georg. i. 404 (a meteorological passage, describing various signs of fine weather).

Apparet liquido sublimis in aëre Nisus.

"Nisus (the hawk) is seen high up in the liquid air."

(*b*) Æneid vi. 202 (where the author is speaking of the sacred doves which conducted Æneas to the golden branch which was to be his "open sesame" to the infernal regions).

Tollunt se celeres, liquidumque per aëra lapsæ
Sedibus optatis geminæ super arbore sidunt.

"Swiftly they soar aloft; then, dropping through the liquid air, together settle on the wished-for tree."

Virgil does not seem to have made any scientific examination of the substance he terms "liquid air"; but he must have noted its transparency since he makes a point of the visibility of birds through a thick stratum of it, and in the second passage he evidently considers (whether from actual experiment or not must be uncertain) that immersion in it had no effect on the "conducting power" of Venus's doves. H. G. M.

The Sentinel Milk Steriliser.

A RECORD of certain observations upon the action of the "Sentinel" steriliser is given in your issue of December 13 (p. 166).

The results of the temperature determinations are there stated as follows:—

		Bell Form.		Cut-off Form.
Water	Half pint	94° and 95° C.	....	95° and 93° C.
	One pint	87·5° ,, 89°	....	86° ,, 87°
	Two pints	87° ,, 86°	....	84° ,, 85°
Milk	Half pint	98° (frothing)	....	95°
	Two pints	87°	....	84°

and your reviewer adds: "It will thus be seen that there is considerable variation in the temperature."

We trust that you will allow us to point out that the instrument used was of the size designed for the sterilisation of *two* pints of milk. An inspection of the above table proves that the apparatus worked in a satisfactory manner even when *one* pint only was placed in the vessel (the temperature readings being 87° to 89° in the bell form and 86° to 87° in the cut-off apparatus), and also that when the proper volume of liquid was inserted, the variations in temperature were still further reduced.

As the apparatus is purposely made in different sizes, and as it was at no time supposed that any one size would be used with but one-quarter of the correct volume of liquid, the conclusion that "there is considerable variation in temperature" certainly conveys a wrong impression to the reader.

Your reviewer appears to doubt the wisdom of selecting temperatures in the neighbourhood of 85° C. Now it is generally acknowledged that Prof. Bang, of Copenhagen, is one of the leading authorities on this subject, and therefore we give the following passage from Scurfield's translation of Nocard's "Animal Tuberculosis" (p. 73).

"The extremely well-conducted experiments of Bang have established the fact that the bacilli of tuberculous milk are destroyed with certainty when the milk is heated to 85° C. for five minutes; between 75° and 80° they are sometimes killed, but not always; they resist a temperature of 70°, and are afterwards able to render guinea-pigs and rabbits tuberculous when inoculated into the peritoneum; but their vitality is lowered, and they are no longer able to resist the action of the digestive juices of those animals. At 60° their virulence does not seem to be modified. Galtier has obtained results almost identical with those of Bang."

It is worthy of remark that one practical application of these investigations is to be found in Denmark, where the law compels all dairies that return unconsumed milk to "heat this milk to 85° C. for a short time, and then rapidly cool the same."

(For the Cambridge Sentinel Manufacturing Co., Ltd.),
D. BERRY (manager).

IN the directions for use issued with the "Sentinel" steriliser, it is not stated that the apparatus should be filled or thereabouts; in consequence the variations in temperature with different volumes were tested. It may not always be convenient or

requisite in the household to sterilise the full amount, and unless explicit directions on this point are given, smaller quantities will be treated, with the result indicated. With regard to the thermal death point of the tubercle bacillus, I am acquainted with the researches of Bang, Galtier, de Man, MacFadyean, and others. Undoubtedly 85° C. is a safe temperature, but the claim that the milk is unaltered in flavour and nutritive qualities thereby cannot be substantiated. In view of Theobald Smith's most careful work, which, so far as I know, has not been challenged, it seems that, provided the milk be heated in a closed vessel so that no skin forms on the surface, pasteurisation at 68° C. for 20 minutes will kill the tubercle bacillus with certainty, and this treatment but slightly alters the flavour of the milk. It may be wise to select the higher temperature, but it should not be stated that the milk is practically unaltered thereby.

YOUR REVIEWER.

TYCHONIANA AT PRAGUE.[1]

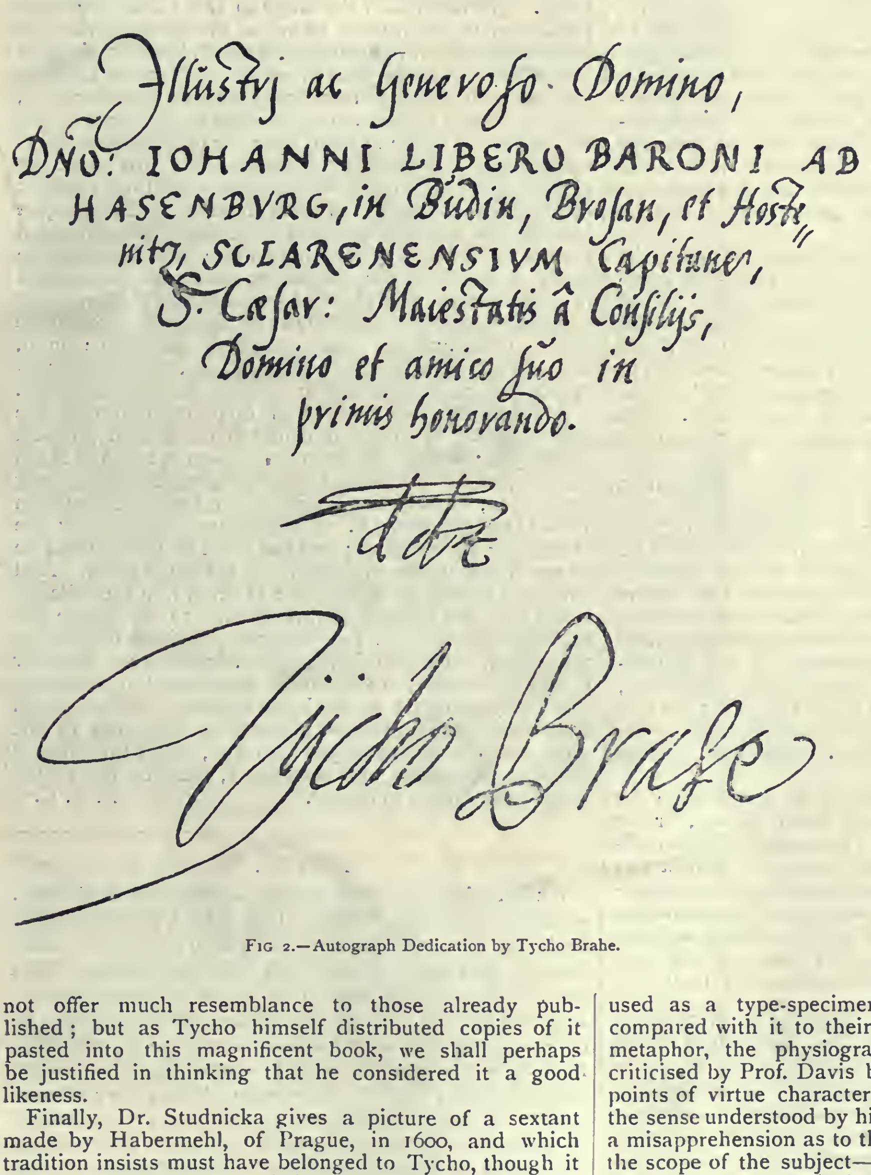
ON October 24, 1901, three hundred years will have elapsed since the death of Tycho Brahe, and this memoir has been published in order to draw attention to that day and at the same time to give some account of the very few relics existing at Prague of the great astronomer, who spent his last years there and whose tomb is in the Teinkirche in that city. Print and illustrations of this memoir are excellent, but we could have wished that the text had been fuller and that at least one of the relics had been discussed in some detail. Tycho Brahe's instruments seem to have been destroyed during the Thirty Years' War, and not one of those he used at Uraniburg has been preserved; his library was scattered, but his manuscript observations fortunately found their way back to Denmark after having been thoroughly utilised by Kepler. The relics at Prague are therefore very modest ones—a few books from his library and a few manuscripts of no great importance. In the library of the Bohemian National Museum there is an album which Tycho gave his eldest son in 1599; on the first page of it is a portrait of the astronomer, reproduced in the present memoir. It is the well-known engraving by Geyn, coloured by hand. The book contains an autograph dedication by Tycho and a picture of his family arms, both of which Dr. Studnicka gives in facsimile. In the University Library there is a more important MS., containing on twenty leaves a short text-book on trigonometry, dated 1591. This was published in 1886 in photolithographic facsimile by Dr. Studnicka, who is exceedingly irritated with the writer of this review for having ventured to say that "Tycho has written his name under the title of the MS., but the handwriting of the remainder does not seem to be his." He even insinuates that the writer had perhaps never seen the facsimile reprint when he uttered this shocking heresy. The fact is, that the excellent reprint showed that the MS. in question was written in an extremely legible and distinct hand, while Tycho's astronomical MSS. in Copenhagen are anything but pleasant to wade through, and we are still of the opinion that it is very doubtful (to say the least) whether the MS. in question was written by Tycho himself. But this is really of no consequence, as nobody doubts that he is the author of it. The University Library also possesses a MS. copy of the table of sines of Copernicus, written by Tycho. Of much greater interest is a copy of the edition of Ptolemy's works of 1551, on the title-page of which Tycho has written that he bought it at Copenhagen on November 30, 1560, for two thaler. He was barely fourteen years of age when he obtained this standard work, and he made good use of it, as appears from the great number of marginal notes which he entered in it from time to time. We should have liked very much to have learned something about these notes, which doubtless would throw much light on the growth of the owner's knowledge, but

FIG. 1.—Portrait of Tycho Brahe.

[1] "Prager Tychoniana." Gesammelt von Prof. Dr. F. I. Studnicka. 65 pp. 8vo, with a coloured frontispiece and illustrations in the text. (Prague, 1901.)

we are told nothing about the nature of the notes, nor about those written in a copy of the work of Copernicus (the Basle edition of 1566), which are also supposed to be in Tycho's hand.

One of the finest Tychoniana at Prague is a copy of the original edition of the "Astronomiæ Instauratæ Mechanica," printed (apparently in a small number of copies) in 1598. As in several other existing copies, the illustrations in this one have been coloured by hand, and there is a portrait inserted in it of which we are glad to be able to append a copy as well as a copy of the author's dedication to the Bohemian Baron von Hasenburg. As we have already remarked elsewhere ("Tycho Brahe," p. 263), this portrait does



Illustri ac Generoso Domino,
DNO: IOHANNI LIBERO BARONI AB
HASENBVRG, in Budin, Brosan, et Hostinitz,
SCLARENENSIVM Capitaneo,
S. Cæsar: Maiestatis à Consilijs,

primis honorando.

Tycho Brahe

FIG 2.—Autograph Dedication by Tycho Brahe.

not offer much resemblance to those already published; but as Tycho himself distributed copies of it pasted into this magnificent book, we shall perhaps be justified in thinking that he considered it a good likeness.

Finally, Dr. Studnicka gives a picture of a sextant made by Habermehl, of Prague, in 1600, and which tradition insists must have belonged to Tycho, though it has none of the characteristics of his own instruments. Though this memoir does not bring out any new facts, the numerous illustrations in it are very interesting, and it is a pleasant proof of the veneration in which the memory of the great astronomer is held in the country where he finished his career. J. L. E. D.

PHYSIOGRAPHY AND PHYSICAL GEOGRAPHY.

THE progress of science, and human perversity, are jointly responsible for remarkable variations undergone by scientific words and terms with the lapse of time. Natural science, which once comprised all knowledge obtained by experiment and observation, now, as many think, only signifies natural history; physical science includes chemistry; physical astronomy is no longer the astronomy of Kepler, but that of the telescope and spectroscope; and physical geography is gradually assuming the name of physiography without acquiring the breadth of view which characterises this science. An article by Prof. W. M. Davis in the *School Review*, published by the University of Chicago Press, brings this nominal metamorphosis prominently before us. Prof. Davis defines physical geography—or physiography—which he considers as synonymous, as "the study of those features of the earth which are involved in the relation of earth and man; that is, the study of man's physical environment." So far as physical geography is concerned, this statement of its boundary lines is satisfactory, but when Prof. Davis uses the definition as a touchstone to test the character of physiography as understood by the examiners for the Department of Science and Art, he employs a criterion having no logical basis whatever.

Though, unfortunately for precision of scientific expression, physiography is often taken to mean physical geography, especially in the United States, the two departments of knowledge ought to be distinctly recognised as separate and fundamentally different in scope. It is perhaps a little late in the day to insist upon the distinction, for a hybrid has been produced which has commendable features and gives hopes of fertility; but what we do object to is that the hybrid is being used as a type-specimen, and its parents are being compared with it to their own detriment. To drop the metaphor, the physiography of South Kensington is criticised by Prof. Davis because it does not possess the points of virtue characteristic of physical geography in the sense understood by him. As he appears to be under a misapprehension as to the original use of the word and the scope of the subject—an obliquity shared, moreover, by many other physical geographers—it may be worth while to recall the circumstances which led to its adoption.

Until the year 1877 the Department of Science and Art held examinations in physical geography as generally understood. The Education Department also held

examinations in physical geography. Grants in aid of teaching were made for successful candidates by each Department; but it was found that many pupil teachers presented themselves for examination by the Department of Science and Art after they had passed the examination of the Education Department, and they thus earned grants twice over for the same subject. To avoid this duplication, it was decided to limit physical geography to the Education Department, and to give the subject under the Department of Science and Art a wider scope and call it physiography. The subject was instituted in place of physical geography by a minute of the Lords of Committee of Council on Education dated August 15, 1876, and the first examination was held in the following year, the syllabus having been drawn up by Sir Norman Lockyer. The deliberate purpose was to introduce a subject which was not physical geography at all, and to prevent candidates with a knowledge of physical geography only from scoring a success upon their knowledge in the examinations in physiography. If this is remembered, the unreasonableness of criticising the physiography of the Department of Science and Art from the point of view of the physical geographer is at once obvious. There is nothing to justify the occupation of this position, and the comparison made from it has no significance.

The general impression is that Huxley first used the word physiography in the sense in which latter-day advocates of physical geography like to understand it. Prof. Davis commits himself to this opinion in the remark that "the term physiography has been adopted [by the South Kensington authorities] because of Huxley's use of it as a title for a series of lectures in 1869 and 1870." Now, as a matter of fact, this statement is not correct. The subject of the lectures was, as Huxley's disciples know, the Thames and its basin; and when the lectures were published eight years later, some elementary information was added on the movements of the earth and the constitution of the sun, and the title of "Physiography" was given to the book thus brought into existence. This Huxley clearly stated in the preface to his inspiring volume, and he also remarked "I borrowed the title of physiography," but that is usually overlooked. In the interval between the delivery of the lectures and their publication, physiography was adopted by the Department of Science and Art as a subject for examination, and what Huxley really did was to give his book the title of the new subject. The same title—physiography—was used by Prof. Ansted for a book published shortly before Huxley's work.

It therefore appears that there is no justification for fathering the term physiography upon Huxley, or for using the contents of his book "Physiography" as an affidavit testifying to the devolution which the subject has undergone on account of the South Kensington examinations. An acquaintance with the actual circumstances which caused the introduction of the subject and the adoption of its title by Huxley would have enabled Prof. Davis to see the matter in a little better light than that in which he wrote his criticism.

It is, however, not the object here merely to show the weak points of a criticism; that is, after all, a small matter in comparison with the meaning which should be attached to the word physiography. Etymologically considered, physiography is the science which is concerned with the facts and phenomena of the whole of nature, and therefore embraces all the natural and physical sciences. The separate sciences have had their fields of activity staked out, and work is continuously carried on in them; but the boundaries are only marked here and there, and it becomes more difficult to define them every day. The amalgamation of all these interests in a company which aims at increasing natural knowledge, represents in a way the relation between the separate sciences and physiography conceived in the widest spirit. Perhaps a philosopher will one day arise and produce from the discrete collections of scientific facts a structure in which all available material shall be fitted into its true place; and the monument thus erected should be called physiography. Or, using another simile, what is wanted is a Darwin who will trace the complete development of organic and inorganic sciences, and show the mutual relations between the stores of knowledge at present kept in different departments. The work in which this is done will be a work on physiography.

The complete co-ordination of scientific material can, however, only become possible when omniscience is reached; what the apostles of physiography have now to do is to preach the gospel of the study of all natural knowledge. He who limits the study to the causes and consequences of the various forms of the earth's surface is not concerned with physiography at all, but with physical geography. As was pointed out by Sir Norman Lockyer long ago, in passing from geography to physiography, we pass from γῆ to φυσις, from the earth to the universe, and unless that is borne in mind the view of physiography is restricted and unnatural. Considered in this light, the physiography of South Kensington examinations presents characteristics worthy of consideration. The subject includes the main fundamental principles of observational science, and the application of these principles to the study of the earth, the sun, moon, stars and other bodies in the universe. The physical environment of man is not considered as such, and though prominence is given to the earth's crust and the changes which take place in it, the point of view is largely physical, and physical causes rather than anthropomorphic consequences are included.

It will thus be seen that there is no pretence to make the physiography of South Kensington the field of physical geography, whether the latter expression is taken to mean the subject as conceived by the geographers of a former generation, or whether it is given the interpretation Prof. Davis puts upon it. It is of course open to any one to criticise the syllabus; but the point of view should be as much that of the physicist as of the geographer. And whatever is said, let it be borne in mind that the syllabus is the only one existing in this country to encourage the experimental study of the physical principles underlying astronomy, earth-knowledge, and meteorology. Whether it would be better, in view of the meaning attached to the word physiography in the United States, for the South Kensington examiners to discontinue their use of the term, and divide the subject into two, under the titles of physical geography and astronomy, must be left to the proper authorities to decide. R. A. G.

NOTES.

WE learn from the *Times* that on Saturday last Prof. Slaby, of the Charlottenburg Technical High School, gave an interesting lecture before the Emperor of Germany and a distinguished company upon improvements which his former assistant, Count Arco, and himself have made in the art of wireless telegraphy. It has not hitherto been possible to use wireless telegraphy for communicating with several different stations at the same time. Prof. Slaby has now succeeded in overcoming this difficulty, and on Saturday night he communicated from the conference room of the General Electric Company in Berlin with operators in the laboratory of the Technical High School at Charlottenburg and in the works of the General Electric Company at Ober Schönweide. These two stations are distant about two and eight miles respectively from the conference room in which the experiment was conducted. Prof. Slaby used two instruments, both of which were connected with a lightning conductor in the neighbourhood. One of the instruments was made to syntonise exactly with that in the laboratory at Charlottenburg, the other

with the instrument in the works at Ober Schönweide. The experiment was a great success, especially in view of the fact that the greater part of Berlin separated the conference room from one of the stations with which messages were exchanged. The German Emperor displayed the greatest interest in the experiments, and afterwards conversed for some time with Prof. Slaby and Count Arco.

WE much regret to announce that Lord Armstrong, F.R.S., died this morning (December 27), at his seat, Cragside, Rothbury, Northumberland.

LORD KELVIN, Master of the Clothworkers' Company, has accepted an invitation to dine with the governors of the Yorkshire College on February 1, on the occasion of their annual gathering at Leeds. He is expected to deliver an address on textile industries.

IN answer to Lady Warwick's appeal for a millionaire to continue and develop the work of her Women's Agricultural College at Reading, a wealthy gentleman has since come forward with an offer of 50,000*l*. for the hostel.

PROF. F. E. NIPHER, of Washington University, Saint Louis, Missouri, announces that, after many months of failure, he has succeeded in developing a fine reversed photographic picture with the developing bath fully exposed to direct sunlight. The operation lasted a full half-hour, with no trace of fog. The developer was a modification of the hydrochinone, the formula for which is given in every box of "Cramer" plates. The bromide was left out, and the sodium carbonate solution was made up at half the strength used for negatives. The mixed developer was diluted with water in the proportion of one part to nine.

MR. W. ERNEST COOKE, Government Astronomer of Western Australia, sends us an account of observations of November meteors, made by Mr. W. C. Best near Newcastle (W.A.), on November 10, at about 9.30 p.m. Mr. Best says:—"The meteors appeared to come from a north-easterly direction and went toward the north. They all seemed to come from one point and spread out as they travelled, each one leaving a streak of light to mark its course. From the point where they started to where they disappeared seemed about 5° or 6°. The display lasted about 30 secs., during which time I saw from 100 to 200 stars shoot."

MR. SOWERBY WALLIS, who was for nearly thirty years associated with the late Mr. G. J. Symons, F.R.S., and has since the latter's death carried on the British Rainfall Organisation, will, from the beginning of next year, be joined in the work by Dr. H. R. Mill, who has resigned the librarianship of the Royal Geographical Society for that purpose.

THE Paris correspondent of the *Chemist and Druggist* states that at the Paris Natural History Museum a laboratory has recently been opened for biological studies applied to the French colonies. The work of the new laboratory will be to reply to inquiries relating to biology, geology and mineralogy, and to prepare precise instructions for foreign correspondents regarding the rearing of animals and cultivation of plants in the respective countries.

OUR attention has been directed to the following surprising announcement, made by the Pekin correspondent of the *Times*: "In pursuance of their regrettable policy of appropriation, the French and German generals, with Count von Waldersee's approval, have removed from the wall of Pekin the superb astronomical instruments, erected two centuries ago by the Jesuit fathers. Half of them will go to Berlin and the rest to Paris. The explanation of this act of vandalism is that, inasmuch as the return of the Court is so improbable, such beautiful instruments should not be exposed to the possibilities of injury when Pekin is no longer the capital."

AN exhibition of photographs by Mr. F. M. Sutcliffe, of Whitby, will be opened on Wednesday next, January 2, in the rooms of the Royal Photographic Society. Admission can be obtained on the presentation of a visiting card.

A NEW meteorological observatory was opened at Aachen (Aix-la-Chapelle) in September last and placed under the superintendence of Dr. P. Polis. From all points of view this establishment is well fitted for carrying on, not only the usual climatological observations, but various researches in atmospherical physics. The last volume of the observations has just been published, for the year 1899, and contains the records for six subsidiary stations, in addition to the records of about thirty rainfall stations, and several valuable discussions, including one on the climate of Aachen. Observations were first commenced in the year 1838 by Dr. Heis, and since 1873 the observatory has formed one of the official stations of the German network. Dr. Polis is a constant contributor to meteorological science in various German periodicals, and we congratulate him upon the establishment of his new observatory and the means now at his disposal for increased usefulness.

THE recent attempts to disperse hail storms by the firing of cannon or mortars, and the suggestion that vortex rings projected by the explosion may be the actual cause which disturbs the storm-cloud, have led Dr. G. Vicentini and Dr. G. Pacher to carry out a series of experiments on the velocity of these so-called "gaseous projectiles." The general conclusions agree with those of Pernter and Trabert, according to which the velocity of these vortices is much smaller than was supposed in the earlier investigations, and this velocity gradually decreases in consequence of viscosity. The authors find that in experiments on a small scale, pistols with a conical barrel give the best results. Some interesting laboratory experiments are described in which a small smoke ring was projected against a target formed of a thin capillary liquid film stretched on a circular frame. The different effects observed, according to the energy of the vortex, include the following: (1) the film bulges out, but returns to its original position, the vortex being arrested; (2) the ring destroys the film and proceeds on its way with diminished velocity; (3) the film is destroyed and the vortex, including most of the smoke, is imprisoned in a bubble which soon falls to the ground; (4) the vortex is imprisoned in a bubble, but the film behind returns to its original position; (5) the bubble which imprisons the vortex remains attached to the film and slowly sinks; (6) the film is destroyed, but the bubble rebounds in the opposite direction to that in which the vortex was projected. These experiments and observations are described in the *Atti del R. Istituto Veneto*, lix. lx.

THE much debated doctrine of partition of energy among the molecules of a gas is once more attacked by Mr. Burbury in the *Philosophical Magazine* for December. The paper consists mainly of an examination of the proofs of the law of equal partition, based on the two alternative methods of Maxwell and Lord Rayleigh, and of Boltzmann respectively, and the conclusions enunciated by Mr. Burbury are as follows: (1) The law of equal partition of energy among the translation velocities is not proved by the Maxwell-Rayleigh method; (2) It is not proved by Boltzmann's method, because the fundamental assumption on which that method is based is not proved; (3) Subject to any proof that may be given hereafter of Boltzmann's assumption, which, however, Mr. Burbury thinks can be disproved, the law is not generally true in any sense whatever. When, however, the density is very small, the mean translational kinetic energies of two molecules of unequal mass will differ only by small quantities of the second order. The law may, therefore, be asserted for the limiting case of an infinitely rar gas.

THE results of a new investigation of the anomalous dispersion of cyanin have recently been published by Dr. C. E. Magnusson in No. 41 of the *Bulletin* of the University of Wisconsin. An attempt has been made to determine the refractive indices throughout the whole spectrum, including the region of the absorption bands, by four distinct methods: (*a*) Direct spectrometer readings in the visible spectrum using solid prisms, the slit being illuminated with monochromatic light produced by an auxiliary spectroscope; (*b*) photographic records of the deviation of a system of monochromatic rays from a Rowland concave grating illuminated by an iron arc; (*c*) a qualitative method, using crossed prisms, and recording the results photographically; (*d*) photographic records of the displacement of the fringes in the Michelson interferometer produced by thin films of cyanin, prepared by dipping plates of glass in alcoholic solutions. To obtain good prisms by Prof. Wood's method, Dr. Magnusson finds that the substance must be heated rapidly, the prism formed and cooled quickly, and at the right temperature; if too cool, the fused mass cannot be pressed between the plates of glass to the required thinness, and if too hot, bubbles make their appearance. The general accordance of the values obtained by the different methods employed results in a fairly accurate dispersion curve for cyanin from the extreme red well into the ultra-violet, and the work with the interferometer gives conclusive evidence of the continuity of the curve through the absorption band in the yellow. It was originally intended to test the Ketteler-Helmholtz dispersion formula for the ultra-violet and extreme red rays, where Pflüger's investigations showed discrepancies. In the case of the ultra-violet it was suggested that the discrepancy might be due to an absorption band, and Dr. Magnusson considers that he has demonstrated the existence of such a band. Until further extensive observations have been made, however, he does not consider a comparison of the new values with the formula likely to be of much service. The results are illustrated graphically, and numerous photographs are reproduced.

AT a meeting of the Anthropological Institute on December 11, Mr. J. W. Crowfoot read a paper on the Bektashis of Cappadocia. Scattered about Turkey in Asia and Persia are many peculiar religious sects, either professing heretical forms of Islam or purely pagan in character, and in both cases hated and persecuted by the orthodox. It has been supposed that the adherents to these sects represent the earliest known inhabitants of the land, and that their religious rites contain relics that go back far beyond the rise of either Mohammedanism or Christianity. With the object of testing this theory, Mr. Crowfoot visited last summer some villages close to the ancient Halys in the Eastern half of Asia minor, occupied by a sect called the Bektash or Kizilbash. Measurements and photographs were taken which corroborate the theory above stated, though evidence was also found of an influx of some more eastern element, driven westwards, probably, at the time of the great Mongol invasions. These people are nominally worshippers of Ali, but in reality the worship of "heroes," from whom they profess descent, plays the greatest *rôle* in their religion. In one village there was a sacred well strongly impregnated with sulphur, and the fumes of this were inhaled by a prophetess who lived there until she fell into an ecstatic condition, in which she used to give answers to the many inquirers who resorted there, either to learn the future or to be cured by the "hero." Other survivals of a similar character were described. Some native weapons from the south-west of Lake Tanganyika, lent by Dr. Felkin, were also exhibited and described at the same meeting.

DR. J. BEARD has sent us a copy of his paper on the morphological continuity of the germ-cells in *Raia batis*, which appeared in the *Anatomischer Anzeiger*, vol. xviii. nos. 20 and 21. Germ-cells appear to be unicellular organisms, passing one stage of their existence within a multicellular sterilised stock, the embryo, which is formed by one of them at a definite period.

MR. E. S. SHRUBSOLE, the curator of the newly-formed Natural History Department at the Crystal Palace, sends us an announcement of the ten "tableaux" of mounted animals he has prepared for exhibition. They are stated to include 15,000 specimens. We are not at present aware of the manner in which they are arranged, but if they are not grouped according to their place of origin, a grand opportunity of familiarising the public with the leading features in geographical distribution will have been thrown away.

WE have received a copy of a memoir by Dr. S. J. Hickson on the Alcyonaria and Hydrocorallinæ of the Cape of Good Hope, published by the Department of Agriculture of the Cape in the series entitled "Marine Investigations in South Africa." Four new species of Alcyonarians are described; but of more importance are certain new investigations the author has been enabled to make into the anatomy of the group, owing to the excellent state of preservation in which the collection was sent to England. As these investigations are not yet completed, the author has published only the systematic work.

RICKETTS in monkeys that have died in captivity forms the subject of a memoir by Signor A Monti, published in the *Memorie* of the Royal Institute of Lombardy (vol. xix., part 3). The author proposes to defer the discussion of the bearing of his observations on zoology to a future occasion; but he claims for them great importance in regard to certain human diseases. For one thing, they definitely controvert the theory advanced by M. Parrot that ricketts in the human species is due to hereditary syphilis.

PHYSIOLOGICAL and pathological heredity in man forms the subject of Dr. T. Oliver's introductory lecture to a course of clinical medicine delivered in the Royal Infirmary at Newcastle-on-Tyne on October 31, a copy of which we have received from the *Lancet* office. The lecturer takes as his example of heredity the modern racehorse, and states that while none but thoroughbreds have won the Derby, no gelding has ever been first past the winning post, and that in all high-class races mares are much less frequently successful than stallions, although it should be added that they are less frequently entered. In one part of his discourse, Dr. Oliver touches upon the question of "telegony," which, in spite of the Penycuick experiments, he appears to think may not be a myth.

FROM Mr. G. E. H. Barrett-Hamilton we have received copies of five papers, four of which deal with local variation in European species of mammals. With one exception (from the *Annals of Natural History*) these latter are taken from the *Proceedings* of the Zoological Society. The species dealt with are the mountain or variable hare, the wood-mouse, weasel, hedgehog, and dormice. Of the first of these no less than eighteen local races are recognised, several being described for the first time. In districts where it normally turns white in winter the weasel is regarded as subspecifically distinct from the form which remains brown at all seasons. The fifth paper received from Mr. Hamilton is from the *Ibis*, and deals with the birds observed by him in Kamschatka in 1896 and 1897. The most important paragraphs in this communication are those dealing with colour and migration.

THE greater portion of the December issue of the *Zoologist* is taken up with a discussion on conscious protective resemblance in animals. Mr. G. A. K. Marshall commences the discussion with criticisms on Mr. Distant's articles on mimicry which appeared some time ago in the same journal. First of all he expresses the opinion that the term "mimicry" should be

restricted to resemblances assumed for the purpose of attracting attention; resemblances for the purpose of concealment being denoted by the terms protective and aggressive resemblance. He then proceeds to inquire whether any of such resemblances can be rightly termed conscious, concluding that the only instance which affords anything like proof of consciousness is one narrated by Mr. E. Thompson concerning the actions of a fox. But even if this be a true instance, the fox is such an abnormally clever animal that the case does not affect other supposed examples; and it is concluded that "there are good grounds for opposing the suggestion that active mimicry is of any general occurrence in the animal kingdom." Prof. E. B. Poulton continues the discussion in the form of notes, in which he gives a general support to the views of Mr. Marshall. Incidentally he mentions that the posture usually given to the leaf-butterfly (Callima) is incorrect. Mr. Distant adds a few remarks in defence of his own views, stating that the questions at issue are largely matters of opinion.

WE have received the first part of a new work by Prof. Der Vries, of Amsterdam, entitled "Die Mutations Theorie." It deals with the origin of new species; and these the author considers to arise solely as the result of sudden sporting, or of discontinuous variation. He does not regard the ordinary variation usually to be observed amongst the individuals of any given race as contributing towards the evolution of new species, but looks upon them as the transient and easily reversible expression of altered circumstances of life. The latter part of the book is occupied with an account of his observations on the "mutations" exhibited by *Œnothera Lamarckiana*, and he claims to have secured a number of discontinuously produced forms which retain their character in successive generations, and which show no tendency towards reversal, nor to the production of forms intermediate between themselves and the parent stock. Even if one does not feel inclined to accept all the author's conclusions, and even if lurking doubts as to the actual purity of the original strain of his Œnothera obtrude themselves on the mind of the reader, the book is worth a perusal for the sake of the lucid manner with which the arguments and facts are brought forward, and (sometimes) constrained to give support to the views therein advocated. It would be, however, premature to discuss the theory as a whole until the completion of the book enables one to form a mature estimate of its real value.

THE November *Journal* of the Royal Horticultural Society provides students of botany and others interested in problems of evolution with plenty of material for thought. Among the subjects dealt with in papers are the evolution of plants illustrated by the cultivated nature of gardens, by Mr. R. I. Lynch; problems of heredity as a subject for horticultural investigation, by Mr. W. Bateson, F.R.S.; aquatic plants, by Prof. G. S. Boulger; protoplasm, the instrument of evolution among plants, by the Rev. G. Henslow, who also contributes several instructive papers on plant structure and growth; the strawberry and gooseberry mildews, by Mr. E. S. Salmon, and descriptions of new plants exhibited at the meetings of the Society. Every one concerned with the science or the art of gardening will find in the *Journal* much suggestive and interesting information.

As a handy compendium of biographical particulars referring to men and women whose names are known in the worlds of literature, art or science, or who are distinguished in other ways, "Who's Who?" now stands alone, for with the 1901 edition, which Messrs. A. and C. Black have just published, is incorporated "Men and Women of the Time." The annual is a good index to the works, recreations and careers of practically every one alive whose influence upon human progress is recognised. All the living Fellows of the Royal Society appear to be included among the biographies, as well as numerous members of other scientific societies. The information tabulated before the biographies includes lists of abbreviations, peculiarly-pronounced proper names, the names and addresses of the chief newspapers and magazines, pseudonyms and pen-names, Fellows of the Royal Society, names, addresses and conditions of admission to scientific and other learned societies, chairs and professors in the universities, university degrees, and other matters of general interest. In the abbreviations we notice "anat.," signifying anatomy or anatomical, and "bot." for botany; but it is not easy to understand why these should be given, while other conventional abridgments, such as "math." for mathematics, "astr." for astronomy, "mech." for mechanics, "mag." for magnetism or magazine, "phys." for physical, "soc." for society," and "phil." for philosophical, are not explained. Either "anat." and "bot." should be omitted or others in just as common use should be inserted. The principle which has led to the selection of other abbreviations is also not clear. We find A.K.C. signifying Associate of King's College, and K.C. for King's College; but we do not see A.R.C.S. for Associate of the Royal College of Science, or U.C. for University College. B. Eng. is given for Bachelor of Engineering, but B.E. is the form usually adopted. D.Sc. is given, but not Sc.D.; and M.I.M.E. (Member of the Institution of Mechanical Engineers) is also omitted, while fellowship of the unrecognised Society of Science and Art is dignified by F.S.Sc.A. In the next edition the professors in the universities of London and Birmingham ought to be added to the list of those occupying chairs in the older universities.

THE additions to the Zoological Society's Gardens during the past week include a Cuvier's Gazelle (*Gazella Cuvieri*) from Algeria, presented by Mr. B. T. Barneby; a Golden Eagle (*Aquila chrysaëtus*) from Scotland, presented by Mr. H. E. Bury; a Rose Hill Parrakeet (*Platycercus eximius*) from Australia, presented by Mrs. Stoughton; a Burmese Tortoise (*Testudo elongata*) from Burmah, presented by Captain A. Pam; a Slow Loris (*Nycticebus tardigradus*) from the Malay Peninsula, three Ring-tailed Coatis (*Nasua rufa*) from South America, a Maximilian Parrot (*Pionus maximiliana*) from Brazil, two Lettered Aracaris (*Pteroglossus inscriptus*) from Para, two Adelaide Parrakeets (*Platycercus adelaidae*), four Plumed Ground Doves (*Geophaps plumifera*) from Australia, two Common Cassowaries (*Casuarius galeatus*) from Ceram, an Ural Owl (*Syrnium uralensis*), a Passerine Owl (*Glaucidium passerinum*), European, five Chestnut-bellied Finches (*Munia rubro-nigra*), six Bungoma River Turtles (*Emyda granosa*), a Roofed Terrapin (*Kachuga tectum*) from India, two Leopard Tortoises (*Testudo pardalis*) from South Africa, a South Albemarle Tortoise (*Testudo vicina*) from South Albemarle Island, three Wrinkled Terrapins (*Chrysemys scripta rugosa*) from the West Indies, a Muhlenberg's Terrapin (*Clemmys muhlenbergi*) from North America, an European Pond Tortoise (*Emys orbicularis*), European, deposited.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN JANUARY, 1901.

Jan. 2–3. Epoch of the January meteors (Radiant $230° + 53°$).
3. 9h. Venus in conjunction with Neptune. Venus $1° 10'$ N.
3. 11h. 7m. Minimum of Algol (β Persei).
5. 9h. 45m. to 10h. 50m. Moon occults 1 Cancri (mag. 5·9).
6. 6h. 36m. to 7h. 31m. Moon occults A^1 Cancri, (mag. 5·6).
6. 7h. 56m. Minimum of Algol (β Persei).
6. 13h. 48m. to 15h. 4m. Moon occults 60 Cancri, (mag. 5·7).
9. 4h. 45m. Minimum of Algol (β Persei).
15. 9h. Venus in conjunction with Jupiter. Venus $0° 22'$ N.

Jan. 15. Venus. Illuminated portion of disc = 0·902, Mars = 0·949.

17. 21h. Jupiter in conjunction with moon. Jupiter 2° 13′ S.

18. 2h. Venus in conjunction with moon. Venus 2° 12′ S.

18. 16h. Saturn in conjunction with moon. Saturn 2° 41′ S.

19. 18h. 37m. to 21h. 21m. Transit of Jupiter's Sat. III.

24. 8h. Venus in conjunction with Saturn. Venus 0° 20′ S.

28. 8h. 3m. to 8h. 28m. Moon occults 13 Tauri (mag. 5·4).

29. 6h. 0m. to 6h. 37m. Moon occults DM+20°, 785 (mag. 5·8).

30. 14h. 41m. to 15h. 36m. Moon occults χ^1 Orionis (mag. 4·7).

EPHEMERIS FOR OBSERVATIONS OF EROS.—The following is an abridgment of Herr Millosevich's ephemeris for January:—

Ephemeris for 12h. Berlin Mean Time.

1901.	R.A. h. m. s.	Decl. ° ′ ″	Mag.
Jan. 1	2 3 52·80	+37 55 14·5	
3	9 2·80	37 3 39·5	8·44
5	14 27·17	36 12 7·3	
7	20 4·92	35 20 39·0	8·45
9	25 55·21	34 29 15·8	
11	31 57·23	33 37 59·2	8·45
13	38 10·17	32 46 50·5	
15	44 33·19	31 55 51·2	8·46

DIAMETER OF VENUS.—In the *Astronomische Nachrichten* (Bd. 154, No. 3676) Prof. T. J. J. See announces the results of a long series of measurements of the diameter of Venus, made with the filar-micrometer on the 26-inch refractor of the U.S. Naval Observatory at Washington. He also prefaces his remarks by a *résumé* of the observations of the diameter which have been made since the time of Galileo (1620).

The difficulties of the determination are summarised thus:—

(1) The enormous change in the geocentric distance of the planet renders the apparent diameter extremely variable.

(2) The thin line-like horns presented when the planet is near inferior conjunction are easily affected by atmospheric disturbances, rendering bisection with the micrometer wire difficult.

(3) As the crescent enlarges the diameter decreases.

(4) Near superior conjunction, although the disc is nearly round, its diameter is so small, and the time of observation is necessarily such that the heated atmosphere has a great disturbing effect on the definition.

(6) Irradiation, which is always great on account of the brilliancy of the planet.

Much of the difficulty due to the brilliancy has been eliminated by the use of coloured screens between the eye and telescope, as described in *A.N.* Nos. 3636, 3665.

The mean of Prof. See's determinations on 22 days gives a mean diameter of

$$16''·80^{\circ} \pm 0''·022$$

which is in close agreement with the value 16·820 deduced by Dr. Auwers in 1894 from the transits of Venus in 1874 and 1882.

Several suggestions are included comparing the work with heliometer and filar micrometer on planetary diameters, the two giving variable results with different planets.

REDUCTION OF OCCULTATIONS.—M. L. Cruls, director of the Observatory of Rio Janeiro, has published an improved method of time determination from lunar occultations, based on the exact knowledge of the instant of apparent conjunction of the two bodies. The formulæ of Bessel are slightly modified, and both analytical and graphical solutions given at length, with examples of each.

NATURAL AND ARTIFICIAL PERFUMES.

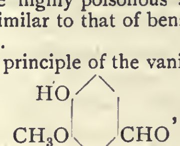
THE passing century has seen the rise and subsequent decay of several great branches of chemical industry. Early in the century, when the chemical methods applicable to the manufacture of alkalis and of alkali products were being actively developed, profits were large, whilst now that the chemical difficulties encountered in the manufacture of alkali have been practically overcome, the financial prosperity of an alkali works depends mainly upon economy in carrying out certain engineering processes; the science of the chemist is now of rather less importance than the art of the engineer. The younger industry of coal-tar dye-stuff manufacture is similarly, though more gradually, developing into a branch of engineering, and in consequence money is not made so rapidly as was once the case. During the last twenty-five years a new chemical industry, that concerned with artificial perfumes, has made rapid progress and would seem to give more promise of both chemical and financial prosperity than either of its elder sisters. Perfumes are only needed in small quantities, but, in accordance with the law that anything ministering to our pleasures fetches a far higher price than a mere article of utility, profits upon a really gigantic scale may be easily obtained; again, the enduring chemical prosperity of the new industry is assured in that a constant succession of new perfumes is absolutely necessary; by the time that improved methods of manufacture and competing processes have lowered the price of a perfume, the material has become unfashionable. No lady would use a cheap perfume. Further, the sense of smell in man is as yet wholly uncultured; in walking through the country we can rarely identify a particular odour caught until the sight of the plant from which it emanates makes us wonder at our hesitation. The coal-tar colour industry found us provided with a highly-developed system of colour perception, whilst the newly-inaugurated artificial perfume industry has to cultivate a neglected sense probably possessing similar artistic potentialities.

The scientific methods adopted in the new industry consist, in the main, of three: (1) in the extraction of odoriferous compounds from the natural products in which they occur; (2) in the artificial preparation of naturally occurring odoriferous compounds by synthetic processes; and (3) in the manufacture of materials possessing odours resembling those of naturally occurring substances of pleasant smell. The odoriferous principle of bitter almond oil was one of the first isolated and subsequently synthesised; the oil was obtained during the Middle Ages by distilling bitter almonds with water, whilst, nowadays, only very small quantities are prepared from the almond. Apricot kernels are first freed from fatty oils by hydraulic pressure, and then caused to undergo a fermentative process. The kernels contain a glucoside, amygdalin, which, at a suitable temperature, is hydrolysed by an unorganised ferment, emulsin, also present, with formation of benzaldehyde, $C_6H_5.CHO$, hydrogen cyanide and grape sugar, in accordance with the equation

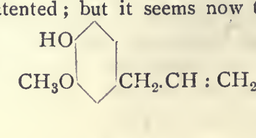
$$C_{20}H_{27}NO_{11} + 2H_2O = C_6H_5.CHO + 2C_6H_{12}O_6 + HCN.$$

The mass is then distilled in a current of steam, and the resulting oil separated from the aqueous distillate and freed from the prussic acid which it still retains. Liebig and Woehler first separated pure benzaldehyde from crude bitter almond oil in 1832. Benzaldehyde is prepared on a large scale by the hydrolysis and oxidation of benzyl chloride by boiling it with cupric or lead chloride solution; the artificial oil retains with great tenacity traces of benzyl chloride, and the penetrating, unpleasant odour of this impurity renders the product fit only for scenting common soaps and prevents its use in perfumery. Nitrobenzene, $C_6H_5.NO_2$, the highly poisonous so-called oil of mirbane, has an odour very similar to that of benzaldehyde, and is sometimes used in its place.

Vanillin, the odoriferous principle of the vanilla bean, is an aldehyde of the constitution

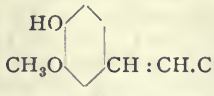


, and was artificially prepared in 1874 by Tiemann and Haarmann; the original method of preparation consisted in oxidising coniferin, a glucoside contained in the sap of various coniferæ, with chromic acid. Many different methods of preparing vanillin have been patented; but it seems now to be mainly obtained from eugenol,

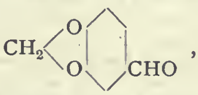


a phenol contained

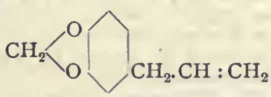
to the extent of 70 to 90 per cent. in oil of cloves; this is heated with alkali, which converts it into isoeugenol



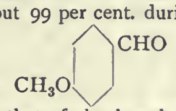
and the latter is then oxidised to vanillin. Synthetic vanillin has practically displaced the vanilla bean for use in perfumery and the manufacture of confectionery, and, in spite of frequent adulteration with sugar, acetanilide and other comparatively valueless materials, the price of the genuine synthetic article is now only a little more than 1 per cent. of that obtained in 1876. The nearly related aldehyde, piperonal,



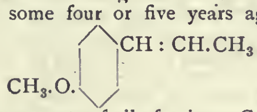
which has a very powerful odour resembling that of the heliotrope, and is consequently used in perfumery under the name of "heliotropin," is largely prepared from safrole



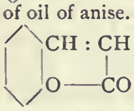
a methylenic ether contained in oil of sassafras and oil of camphor; its price has dropped by about 99 per cent. during the last twenty years. Anisic aldehyde,



which has an intense odour resembling that of the hawthorn flower, was greatly in use some four or five years ago; it is prepared from anethol,



the ether constituting 80 or 90 per cent. of oil of anise. Coumarin, orthohydroxycinnamic anhydride,



is the material to which the tonka bean, sweet woodruff and new-mown hay owe their characteristic odours; it was synthetically prepared by W. H. Perkin, sen., in 1868, by heating sodiosalicylic aldehyde with acetic anhydride, and was obtained commercially by this method until its recent discovery in considerable quantities in *Liatris odoratissima*, a herb indigenous to Florida, provided a cheaper method of preparation. The pleasant smell of cassia oil is due to its containing from 75 to 90 per cent. of cinnamic aldehyde, $C_6H_5.CH:CH.CHO$, which was first synthesised by Strecker; the aldehyde is readily obtained by condensing benzaldehyde with acetaldehyde in presence of soda; and has, indeed, been commercially obtained by this method at times when the Chinese cassia oil distillers adulterated the oil to too great an extent with petroleum, resin, &c.

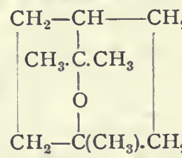
The greater number of the ethereal oils prized in perfumery owe their pleasant odours, not to one constituent alone, but to several, and the smell of the more valuable, such as lavender oil, rose oil, Ylang-Ylang, &c., is a blend of the odours of a number of odoriferous components; the determination of these constituents and their preparation in a state of purity with a view to an ultimate successful imitation of particular ethereal oils has long constituted one of the most intricate problems of industrial chemistry, one, however, which has been attacked with astonishing success. A few of the more important odoriferous principles may be briefly discussed. The aldehyde citral or geranial, $C(CH_3)_2:CH.CH_2.CH_2.C(CH_3):CH.CHO$, constitutes about 6 per cent. of oil of lemons and about 80 per cent. of lemongrass oil, and gives to these oils their lemon-like odour; it is largely prepared, commercially, from lemongrass oil, and is accompanied in nature by its dihydro-derivative, citronellal, $C(CH_3)_2:CH.CH_2.CH_2.CH(CH_3).CH_2.CHO$. Citral was synthesised from acetoacetic ether by Tiemann in 1898, and is converted by reduction into the alcohol, geraniol,

$$C(CH_3)_2:CH.CH_2.CH_2.C(CH_3):CH.CH_2.OH.$$

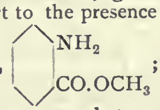
Similarly, citronellal yields on reduction the corresponding alcohol, citronellol,

$$C(CH_3)_2:CH.CH_2.CH_2.CH(CH_3).CH_2.CH_2.OH;$$

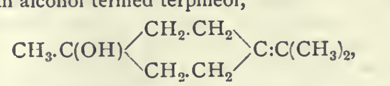
geraniol, further, can be converted into an isomeric alcohol, linalool, $C(CH_3)_2:CH.CH_2\,CH_2.C(CH_3)(OH).CH:CH_2$, by heating with water. These three alcohols, geraniol, citronellol and linalool, yield esters with acids, such, for example, as linalyl acetate, $C(CH_3)_2:CH.CH_2.CH_2.C(CH_3)\Big\langle{CH:CH_2 \atop O.CO.CH_3}$. These aldehydes and alcohols, together with a number of the esters formed with fatty acids, occur in many ethereal oils. French oil of lavender is distilled from wild lavender in the hills of southern France, and contains 30 to 40 per cent. of linalyl acetate and about an equal quantity of linalool and small quantities of geraniol; English oil of lavender is distilled from the cultivated plant, and contains only 5 to 10 per cent. of linalyl acetate, but considerable amounts of cineol,



The fact that English oil fetches about ten times the price of the best French oil is a frequent source of unfavourable comment by Continental merchants. Ylang-Ylang oil contains linalool and geraniol, and apparently also the acetic and benzoic esters of both alcohols; the similar, though less valuable, Cananga oil contains smaller quantities of the esters and larger quantities of a sesquiterpene, $C_{15}H_{24}$. Otto of roses, which has for centuries been the most highly prized of all perfume oils, is obtained in the East, in Bulgaria, Germany and, to a small extent, in France, by distilling freshly-gathered roses with water; it contains a wax-like hydrocarbon, the so-called stereoptene, and during the last month Walbaum and Stephan have shown that German rose oil owes its odour to geraniol, citral, citronellol, linalool, nonylic aldehyde, $C_9H_{19}.CHO$, and phenylethylic alcohol, $C_6H_5.CH_2.CH_2.OH$. It is interesting to note that Neroli oil, which contains linalool, geraniol and linalyl acetate, owes its odour in part to the presence of a small percentage of methyl anthranilate,

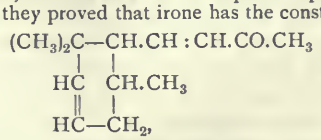


; this substance, in an undiluted condition, has a somewhat unpleasant odour, but when highly diluted smells very much like oil of bitter orange. An alcohol termed terpineol,



is found in many essential oils, and is readily and cheaply prepared by the action of dehydrating agents upon terpin hydrate, which in turn is easily prepared from turpentine oil; terpineol has a powerful odour of lilac, and consequently finds extensive application as a basis in the manufacture of perfumes.

Oil of orris, mainly obtained from Italian orris root, consists, to the extent of about 35 per cent., of the odourless myristic acid. In 1893 Tiemann and Krueger showed that the odour of fresh violets possessed by the oil is due to the presence of a small proportion of a ketone to which they gave the name irone; as the result of an important piece of experimental work, they proved that irone has the constitution

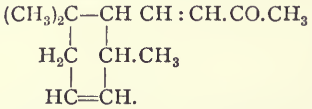


and a patent was obtained by Haarmann and Reimer for a method of separating this ketone from oil of orris. Tiemann and Krueger, before actually ascertaining the constitution of irone, conceiving the possibility of preparing a substance of the same molecular composition as irone from citral, endeavoured to do so in order to obtain information as to the constitution of the ketone. They found that, on allowing a mixture of citral and acetone to remain in contact with baryta solution, an

ordinary acetone condensation slowly occurs with formation of a ketone, the so-called pseudoionone, having the constitution

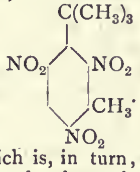
$CH(CH_3)_2.CH_2.CH:CH.C(CH_3):CH.CH:CH.CO.CH_3$.

Pseudoionone has a peculiar but not very pronounced smell, and, when heated with a mixture of water, glycerol and sulphuric acid, undergoes conversion into an isomeric ketone, termed ionone, which possesses the constitution



Ionone possesses an odour of fresh violets, which also feebly recalls that of grape blossom; it is manufactured on a large scale for use in the preparation of violet perfumes. The preparation of homologues of ionone from citral and methylethylketone has also been protected, and numerous attempts to evade the original patents have naturally been made; the use of lemongrass oil in place of citral, and of bleaching powder as a condensing agent in place of baryta, have been patented, but these patents have not been upheld by the Courts. It is a very remarkable fact that the two ketones, irone and ionone, possess odours so similar that, either when pure or diluted with alcohol, a trained nose is only just able to distinguish between them. The similarity in odour is doubtless due to the almost identical type of molecular grouping contained in the two compounds. Oil of turpentine consists essentially of a hydrocarbon of similar molecular type to irone and ionone, and it is a very noteworthy fact that turpentine, when administered internally, imparts a strong odour of violets to the urine; so far as can be ascertained, this fact has received no commercial application.

A number of substances have been introduced into commerce as substitutes for musk; of these, the first was the trinitroisobutyltoluene of the constitution



It is obtained by nitrating isobutyltoluene, which is, in turn, prepared by the interaction of isobutyl chloride and toluene brought about by aluminium chloride. This and other trinitro-derivatives of benzenoid hydrocarbons containing two alkyl groups in the meta-position possess a powerful odour of musk, and have been used to a considerable extent in perfumery.

The investigation and manufacture of artificial and synthetic perfume materials have been only carried on to a very small extent in this country; the new industry is almost wholly of German origin. During recent years, however, France appears to have been making great strides in synthetic perfume manufacture, and at the Paris exhibition this branch of chemical manufacture seems to be the only one in which the French exhibits equal, or even excel, those of Germany. The cause of this is obscure, but may possibly be connected with the generally recognised principle that supremacy in any particular industry goes hand in hand with supremacy in the related sciences; and all students of contemporary chemical literature will agree that in Germany the science of chemistry has been in rapid decadence during recent years. A good organisation, administered by a master, accomplishes great results; but when the directing hand is gone, the very organisation itself is found to have stultified the faculty for independent thought on the part of those originally destined by nature to take the lead. Subsequently the system aids only in the filling up of immaterial details, and the pioneer work is transferred to men from quite a different school.

Little has yet been accomplished towards ascertaining the relation between the odour and the chemical constitution of substances in general. Hydrocarbons as a class possess considerable similarity in odour, so also do the organic sulphides and, to a much smaller extent, the ketones. The subject waits for some one to correlate its various physiological, psychological and physical aspects in the same way that Helmholtz did for sound. It seems, as yet, impossible to assign any probable reason to the fact that many substances have a pleasant odour. It may, however, be worth suggesting that certain compounds, such as the volatile sulphides and the indoles, have very unpleasant odours because they are normal constituents of mammalian excreta and of putrefied animal products; the repulsive odours may be simply necessary results of evolutionary processes. W. J. P.

PRIZE LIST OF THE ACADEMY OF SCIENCES.

AT the annual public meeting of the Paris Academy of Sciences, on December 17, after the Presidential Address of M. Maurice Lévy, in which was a short account of the life work of MM. Milne-Edwards, Bertrand, Blanchard and Grimaux, the list of awards for the year 1900 was given.

In Geometry, the Grand Prize of the Mathematical Sciences was awarded to M. Mathias Lerch for work on the number of certain classes of quadratic forms; the Francœur Prize to M. Edmond Maillet, and the Poncelet Prize to M. Léon Lecornu. No memoir was received complying with the terms of the Bordin Prize. In Mechanics, the Extraordinary Prize of 6000 francs was divided between MM. Laubeuf, Charbonnier, Aubusson de Cavarlay and Grasset, M. Lerosey receiving the Montyon Prize, and Mme. Moissenet the Plumey Prize as a mark of esteem for the work done by her late husband.

In Astronomy, the Lalande Prize was adjudged to M. Giacobini for his work on comets; the Damoiseau Prize to M. J. von Hepperger for his work on the influence of the planets upon comets: the Valz Prize to M. l'Abbé Verschaffel for work done at the Abbadia Observatory; the Janssen Prize to Prof. Barnard for his brilliant discovery of the fifth satellite of Jupiter.

In Statistics, the Montyon Prize has been awarded to M. du Maroussem, the works of M. Barras, M. Laussedat and M. Pailhas receiving honourable mention.

In Chemistry, M. Béhal receives the Jecker Prize, and in Botany, M. H. Bruchmann the Desmazières Prize, M. Gyula Istvanfi having a very honourable mention. The Montagne Prize is divided between MM. Delacroix and Boistel. In Anatomy and Zoology the Thore Prize is awarded to M. Seurat for his researches on the parasitical larvæ of the Hymenoptera, and the Da Gamo Machado Prize to Mme. la Comtesse de Linden, M. Siedlecki, M. P. Carnot and M. Bordas, the Savigny Prize not being awarded.

In Medicine and Surgery, Montyon Prizes are adjudged to MM. Hallopeau and Leredde, for their treatise on dermatology; M. Guilleminot, for his work on the medical applications of the X-rays; and M. Joules Soury, for his book on the central nervous system. In connection with these prizes, mentions are accorded to M. Nobécourt, for his work on the pathogeny of the gastro-intestinal diseases of young children; M. Sabrazès, for his work on the origin of blood corpuscles; and M. Gallois, for a book on scrofula and odenoidal diseases; MM. Cunéo and Toulouse receiving citations. The Barbier Prize is divided between M. Marage, for a memoir on the theory of vowel formation, and M. Guinard, for a pharmacodynamic study of morphine and apomorphine, a mention being accorded to MM. Bræmer and Suis. In default of the discovery of an absolute specific for cholera, the arrears of interest on the Bréant Prize are divided between M. Auclair, for researches on the toxic substances contained in tubercle bacilli, and M. Paul Remlinger, for a memoir on some rare complications of dysentery, and the association of dysentery with typhoid fever. The Godard Prize is given to M. Léon Bernard, for his researches on the functions of the kidney in chronic nephritis; the Parkin Prize to M. Henri Coupin, for work done in plant physiology; the Dusgate Prize to M. Icard, for methods of diagnosis of real and apparent death; the Baron Larrey Prize to MM. Nimier and Laval, for three works on projectiles and explosives; the Bellion Prize being divided between M. J. Brault, for his treatise on tropical diseases, and M. Samuel Gache, for his treatise on workmen's dwellings in Buenos Ayres; the Lallemand Prize between M. Maurice de Fleury, for various treatises on medicine, and M. de Vabias, for his researches on the nervous system of aquatic gasteropods. Honourable mentions are accorded to MM. Knopf, Jacquet and M. Finck.

In Physiology the Montyon Prize is divided between M. Pachon for studies on cardiac and vascular mechanism and Mdlle. Jotéyko for memoirs on nervous effort and fatigue, and the Philipeaux Prize between M. Delezenne for his reseaches on anti-coagulating substances and M. Nicloux for experimental researches on the elimination of alcohol in the organism, M. Roussy receiving honourable mention; the Pourat Prize is awarded to MM. Bergonié and Sigalas for a determination of the principal anthropometric data; and the Martin-Damourette Prize to M. Long for his studies on the central paths of general sensibility. In Physical Geography, M. Lugeon receives the Gay Prize for his theory on the origin of Alpine valleys.

Among the General Prizes, a Montyon Prize is awarded to

M. Trillat for his applications of formaldehyde to industry, and to MM. Sévène and Cohen for their use of phosphorus sesquisulphide in the manufacture of matches in the place of ordinary phosphorus; the Cuvier Prize to M. Antoine Fritsch for his treatises on European Birds and on Palæontology, the Wilde Prize to M. Delépine, for his experimental researches on aldehydes; the Vaillant to M. Henri Gautier, for his work on alloys and on the atomic weight of boron; and to M. F. Osmond, for his researches on iron and steel; the Frémont Prize to M. Ch. Frémont, for his results on the testing of the resistance of metals; the Gegner Prize to Mme. Curie; the Delalande-Guérineau Prize to M. Maurain and M. Lacombe, for their work on the measurement of an arc of meridian at Quito; the Jérome Ponti Prize to MM. P. Girod and Massénat; the Tchihatchef Prize to M. de Loczy, for work on the Physical Geography and Geology of Eastern China; the Houllevigne Prize to M. Wallerant, for his researches in Crystallography. The Boileau Prize is divided between M. Sautréaux, M. Delemer and M. Nau; the Cahours Prize between M. Mouneyrat, M. Metzner and M. Defacqz.

The Saintour Prize is awarded to M. Debureaux, the prize founded by the Marquise De Laplace to M. Macaux, and the prize founded by M. Félix Rivot to MM. Macaux, de Schlumberger, Martinet and Hardel.

UNITED STATES GEOLOGICAL SURVEY.

THE work of the Geological Survey of the United States comes before us in almost overwhelming amount, and yet, as we take note of the publications, we have no sentiment but that of admiration for the evidence they give of brilliant, useful and painstaking research: research, too, of very varied character.

Bulletins.

A dozen numbers of the *Bulletin*, dated 1898 and 1899, have all been received since midsummer of this year.

Nos. 156 and 162 on the Bibliography of North American Geology for 1897 and 1898, contain the titles with, in many cases, brief notes of the contents of all geological publications dealing with the United States and Canada. Seven hundred and forty-two articles are recorded for 1897, and 941 for 1898. Here, indeed, is the index to a vast amount of information, which to be made available for general reference requires, ultimately, to be tabulated and summarised under many subjects.

Bulletin No. 154 is "A Gazetteer of Kansas," containing a list of all hamlets, post villages and townships, with, as far as possible, notes of their area, population and altitude; the whole prefaced with general statistics. No. 160 is the third edition of "A Dictionary of Altitudes in the United States," a work of 775 pages, arranged alphabetically, according to the localities in the several States. In Nos. 155 and 161 we find records of the earthquakes which happened in California in 1896, 1897 and 1898. A scale, divided into ten numbers, is given for estimating the intensity of shocks Thus No. vi. notes "general awakening of sleepers; general ringing of bells; swinging of chandeliers; stopping of clocks; visible swaying of trees; some nervous persons run out of buildings; window glass broken"; while No. x. tells of "Great disasters; overturning of rocks; fissures in the surface of the ground; mountain slides."

We pass on to other Bulletins, and in No. 152 have "A Catalogue of the Cretaceous and Tertiary Plants of North America," by Mr. F. H. Knowlton; and in No. 152, "A Bibliographic Index of North American Carboniferous Invertebrates," by Mr. Stuart Weller. These works must prove of the greatest value for reference. They are clearly printed, the synonyms are recorded, and there are lists of works on the subjects dealt with.

Other numbers of the Bulletin are of a different character. In No. 151 we have an account of "The Lower Cretaceous Gryphæas of the Texas Region," by Messrs. R. T. Hill and T. W. Vaughan. Fossil oysters have always been regarded as a troublesome and variable group, mainly, as the authors believe, because they have not been properly understood and classified. These fossils are, however, important, not merely from a zoological, but from a stratigraphical point of view, as shown by certain deep borings for artesian water in Texas. Abundant material is to be found in that country for their study. They lie strewn upon the surface in such numbers that they are sometimes used for road material or collected and burned into lime. Extensive masses of indurated strata are composed of them. The pebbles in the streams are largely made up of oysters. They represent many genera and species, and are of all sizes, from individuals less than an inch in length to shells which weigh 5 lbs. and more. They are found at various horizons throughout 4000 and more feet of rocks constituting the Cretaceous system in Texas. There is thus ample material for a study of the fossils from a phylogenetic and morphologic standpoint, and the authors here give their special attention to the Gryphæas. The work is admirably illustrated, and it is not obscured in any way by the indiscriminate naming of specimens.

No. 157, on "The Gneisses, Gabbro-schists and Associated Rocks of South-western Minnesota," by Mr. C. W. Hall, No. 158, on "The Moraines of South-eastern South Dakota," by Mr. J. E. Todd, and No. 159, on "The Geology of Eastern Berkshire County, Massachusetts," by B. K. Emerson, are all well illustrated, full of information of local importance and of much that is of general interest.

Indiana Report.

The geology and natural resources of Indiana are treated of by Mr. W. S. Blatchley, the State geologist, in the twenty-fourth annual report of the department (1899). The volume is one of 1078 pages, and is largely occupied with a catalogue, by Mr. S. Coulter, of the flowering plants and of the ferns and their allies indigenous to Indiana. A considerable portion is also taken by a descriptive and illustrated catalogue of the mollusca of the State, by Mr. R. E. Call. These include a large number of *Unios*. The dragon flies of Indiana are enumerated and described by Mr. E. B. Williamson, and there are notes on the batrachians and reptiles of Vigo county, by Mr. W. S. Blatchley. The economic resources of Indiana include coal, petroleum, natural gas, stone and clays. The amount of natural gas is restricted, and a failure of supply is expected. A great increase of activity in the coal regions is noted. There is estimated to be forty billions of tons of coal in Indiana, of which one-fifth is reckoned as workable under present conditions. Excellent coal for steam and household purposes and for blast-furnaces is obtained. Dr. A F. Foerste contributes an article on the Middle Silurian rocks of the Cincinnati anticlinal.

U.S. Annual Reports.

Parts i., iv. and vi., and portions of Part ii. of the nineteenth annual report were noticed in NATURE for April 19. We have since received Parts ii., iii. and v., four volumes, including an atlas. Part ii., which comprises 958 pages and 172 plates, is somewhat heavy and unwieldy as a work of reference. Of articles not previously noticed, one by Mr. C. W. Hayes deals with the physiography of the Chattanooga district in Tennessee, Georgia and Alabama. The city of Chattanooga lies almost in the centre of this district, and the term physiography is used in a purely geographical sense. The article is an essay on denudation, written according to the principles of modern geography. The author deals with the formation of three successive peneplains, and shows how the drainage has been modified and diverted until the present topographic features were developed. The peneplains are considered as the product of subaërial erosion. The term geomorphology is used for the description, classification and correlation of the land forms; and geomorphogeny for the natural processes by which these forms have been developed. The author gives definitions of other physiographic terms, which are being introduced at a somewhat alarming rate.

Another article in Part ii. is on the Geology of the Richmond Basin, Virginia, by Messrs. N. S. Shaler and J. B. Woodworth. The area is important from an economic point of view as it contains the only free-burning coal immediately adjacent to tidewater in the eastern portion of the United States. The strata are of Jura-Trias age, the fossils from the lower portion of them being more closely related to the Rhætic deposits of Europe than to those of any other horizon. The beds are grouped as the Newark formation, and they rest locally on a surface of igneous and crystalline rocks. Natural coke occurs in the strata, and is due to the intrusion of igneous rocks; it is denser than artificial coke. The bituminous coals are sharply parted from the cokes as the effects produced by the igneous rocks end abruptly. Mr. F. H. Knowlton contributes some notes on fossil coniferous wood from the Richmond Basin.

In Part v. the subject of Forest Reserves is elaborately dealt with by Mr. Henry Gannet and others. An endeavour is made to estimate the present amount of woodland distributed in the different States. Texas has the largest area, of about 64,000 square miles, while Arkansas has the largest percentage of woodland. The question of the protection of forests is one that is engaging much attention, so that the statistics and general information here brought together must be of great value. The report is illustrated by an atlas.

Of the Twentieth Annual Report we have received Part i. and Part vi. (2 vols.). Part i. contains the report of the Director, Mr. Charles D. Walcott, an admirable record of systematic work, which evidently receives the sympathy and substantial support of Congress. The appendix contains details of triangulation and spirit-levelling, and the work is accompanied by maps showing the progress of the surveys. Part vi. is on the Mineral Resources for 1898, the subject being under the direction of Mr. David T. Day. The total value of the mineral productions is the largest ever recorded in the history of the United States. All the metals, except nickel, made large gains, copper, lead, zinc, aluminium and antimony reaching their maximum, both in production and value. The amount of pig-iron produced was greater than in any other year, but the value was less. The non-metallic products also show an increase, especially bituminous coal, and in a lesser degree stone, petroleum and natural gas. The coal product amounted to about two hundred millions of tons.

Monographs.

Monograph No. 32, Part ii., is a large and handsome volume on the Geology of the Yellowstone National Park, by Mr. Arnold Hague and numerous colleagues. It opens with an account, by Messrs. J. P. Iddings and W. H. Weed, of the Gallatin Mountains, which consist of sedimentary strata ranging from Cambrian to Carboniferous, Jura-Trias, and Cretaceous (Laramie). Disturbances at the close of the Laramie formation were accompanied by igneous intrusions in the form of large laccolites, mainly andesitic in character. Electric Peak and Sepulchre Mountain are described as parts of a Tertiary volcano which was faulted across the conduit, the amount of vertical displacement having been more than 5000 feet.

Mr. Hague describes a mountainous area in the southern part of the Park, comprising ridges formed partly of Palæozoic but chiefly of Cretaceous rocks. The irregular outline of the mountains is due to the rhyolites of the Park Plateau that abut against the slopes of the upturned sedimentary strata. The Snake River hot springs are situated near the contact of the rhyolite with the Madison (Carboniferous) limestone, whence the travertine of the springs is derived. Mr. Iddings gives a particular account of the Miocene volcano of Crandall Basin, which arose on a ridge of Palæozoic rocks and on remnants of Eocene breccias and lava flows. The volcano consisted of andesitic breccias capped by basalt flows and traversed by dykes. It must have risen 13,400 feet above the limestone floor. The igneous rocks of the Absaroka range, and others which lie within Yellowstone Park, are specially dealt with by Mr. Iddings. The Cambrian fossils are described by Mr. C. D. Walcott, the Devonian and Carboniferous by Mr. G. H. Girty, the Mesozoic by Mr. T. W. Stanton, and the Fossil Flora (Laramie and Tertiary) by Mr. F. H. Knowlton.

Monograph No. 33 contains an account of the geology of the Narragansett Basin, a tract which includes Providence on the north and Newport on the south, being parts of Rhode Island and Massachusetts. The section on general geology is contributed by Mr. N. S. Shaler, while the detailed accounts are furnished by Mr. J. B. Woodworth and Dr. A. F. Foerste. Mr. Shaler remarks that the region originally contained an extensively developed series of pre-Cambrian rocks, which "may for convenience be referred to that limbo of ill-discriminated formations, the Upper Archæan (of Dana), or Algonkian." On these lie remnants of the Olenellus-beds of the Lower Cambrian, and above these are granites which have broken through the Cambrian, and have in turn been much eroded. On top lie the Carboniferous strata, which occupy the greater part of the basin and attain a thickness of several thousand feet. The general proposition is that this and other basins which lie along the Atlantic coast from Newfoundland to North Carolina are old river valleys which have been depressed below the sea-level, filled with sediments—the sedimentation increasing the depth of the depression—and afterwards corrugated by the mountain-building forces. The memoir is well illustrated with maps, sections and pictorial plates.

Monograph No. 34 is on the glacial gravels of Maine and their associated deposits, by Mr. George H. Stone. The subject is treated with a wealth of letterpress (499 pages) and illustrations. It is essentially a local memoir, but as the result of careful observations commenced so long ago as 1876, it is a most valuable record of facts on water-assorted glacial drift, useful to those studying glacial features, terraces, eskers and the probable effects of subglacial and englacial streams.

In Monograph No. 36 the Crystal Falls iron-bearing district of Michigan is described by Messrs. J. Morgan Clements and H. Ll. Smyth. This is the third of a series of reports on the iron-bearing districts of Lake Superior. The iron-ore (hæmatite and limonite) occurs in the Upper Huronian series. It is associated with white and reddish chert, and lies between carbonaceous slates in synclinal troughs. The memoir, however, deals with the structure, stratigraphy and physiography of a large area, approximately 540 square miles, and not only with Archæan and Huronian, but more particularly with various volcanic and intrusive rocks, microscopic sections of which form a main feature in the illustrations. A general introduction is written by Mr. C. R. Van Hise, and a final chapter on the Sturgeon River tongue in the south-eastern part of the district is by Mr. W. S. Bayley.

Monograph No. 37 is on the Fossil Flora of the Lower Coal-measures of Missouri, by Mr. David White, and is illustrated by seventy-two plates of Carboniferous plants, and one of a coal-seam.

Monograph No. 38, a large volume of 817 pages, numerous maps and other illustrations, is given up to a description of the Illinois Glacial Lobe, by Mr. Frank Leverett. This ice-tract formed the south-western part of the great ice-field that formerly extended from the high lands east and south of Hudson Bay over the basins of the Great Lakes and the north-central States as far as the Mississippi Valley. It overlapped a previously glaciated region on the south-west, whose drift was derived from ice which moved southward from the central portion of Canada. The evidence for separating the drift of the Illinois glacial lobe from the outlying and underlying drift is briefly stated. Remarkable instances of the transportation of limestone ledges are noted. These ledges in some instances occupy an area of several acres. They have been moved westward from the crest of rock ridges without completely destroying their stratification. Descriptions are given of well-defined soils and weathered zones which occur between successive accumulations of drift; various moraines and associated sheets of till are described, and there is a general discussion on the influence of the drift on drainage systems. The thickness of the Illinois drift is estimated at from 100 to 130 feet, and its bearing on water-supply is fully considered. Reference is made to gas-wells. In some the gas appears to be derived from the decay of vegetable matter in the drift; in most cases, however, it is probable that the underlying rocks contribute the gas, which is pent up beneath compact drift beds. A final chapter treats of soils, and these are classified into residuary soils, boulder-clay soils, gravelly, sandy and bluff-loess soils, silts slowly pervious to water, fine silts nearly impervious, and peaty or organic soils. The residuary soils show variations which correspond in a rude way with variations in the structure of the rocks, whether shale, limestone or sandstone, from which they are derived.

ON THE RELATIONS OF RADIATION TO TEMPERATURE.[1]

THE key to this subject is the principle, arrived at independently by Balfour Stewart and Kirchhoff about the year 1857, that the constitution and intensity of the steady radiation in an enclosure is determined by the temperature of the surrounding bodies, and involves no other element. It was pointed out by Stewart[2] that if the enclosure contains a radiating and absorbing body which is put in motion, the temperature being uniform throughout, then the constitutions of the radiation in front of it and behind it will differ on account of the Doppler effect, so that there will be a chance of gaining mechanical work in the restoration of a uniform state. There must thus be some kind of thermodynamic compensation, which might arise from æthereal friction, or from work required to

1 A paper read by Dr. J. Larmor, F.R.S., before Section A of the British Association at Bradford, September, 1900.

2 *Brit. Assoc. Report*, 1871; *cf.* also *Encyc. Brit.*, art. "Radiation" (1886), by Tait.

produce the motion of the body against pressure excited by the surrounding radiation. The hypothesis of friction is now out of court in ultimate molecular physics; while the thermodynamic bearing of a pressure produced by radiation has been developed by Bartoli and Boltzmann (1884), and that of the Doppler effect by Wien (1893).

Application of the Doppler Principle.—The procedure of Wien amounts to isolating a region of radiation within a perfectly reflecting enclosure, and estimating the average shortening of the constituent wave-lengths produced by a very slow shrinkage of its volume. The argument is, however, much simplified if the enclosure is taken to be spherical and to remain so; for it may then be easily shown that each individual undulation is shortened in the same ratio as is the radius of the enclosure, so that the undulatory content remains similar to itself, with uniformly shortened wave-lengths, whether it is uniformly distributed as regards direction or not, and whatever its constitution may be. But if there is a very small piece of a material radiator in the enclosure, the radiation initially inside will have been reduced by its radiating and absorbing action to that corresponding to its temperature. In that case the shrinkage must retain it always, at each stage of its transformation, in the constitution corresponding to some temperature. Otherwise differences of temperature would be effectively established between the various constituents of the radiation in the enclosure; these could be permanent in the absence of material bodies; but if the latter are present this would involve degradation of their energy, for which there is here no room, because, on the principles of Stewart and Kirchhoff, the state corresponding to given energy and volume and temperature is determinate. Thus we infer that if the wave-lengths of the steady radiation corresponding to any one temperature are all altered in the same ratio, we obtain a distribution which corresponds to some other temperature in every respect except absolute intensities.

Direct Transformation of Mechanical Energy into Radiation.[1]—There is one point, however, that rewards examination. When undulations of any kind are reflected from an advancing wall, there is slightly more energy in the reflected beam than there was in the incident beam, although its length is shorter on account of the Doppler effect. This requires that the undulations must oppose a resistance to the advancing wall, and that the mechanical work required to push on the wall is directly transformed into undulatory energy. In fact, let us consider the mechanism of the reflexion. Suppose the displacement in a directly incident wave-train, with velocity of propagation c, to be $\xi = a \cos (mx - mct)$; that in the reflected train will be $\xi' = a' \cos (m'x + m'ct)$, where a', m' are determined by the condition that the total displacement is annulled at the advancing reflector, because no disturbance penetrates beyond it; therefore, when $x = vt$, where v is its velocity, $\xi + \xi' = 0$. Thus we must have $a' = -a$, and $m' = m\,\dfrac{c-v}{c+v}$, in agreement with the usual statement of the Doppler effect when v is small compared with c. Observe, in fact, that the direct and reflected wave-trains have a system of nodes which travel with velocity v, and that the moving reflector coincides with one of them. Now the velocities $d\xi/dt$ and $d\xi'/dt$ in these two trains are not equal. Their mean squares, on which the kinetic energy per unit length depends, are as m^2 to m'^2. The potential energies per unit length depend on the means of $(d\xi/dx)^2$ and $(d\xi'/dx)^2$, and are of course in the same ratio. Thus the energies per unit length in the direct and reflected trains are as m^2 to m'^2, while the lengths of the trains are as m' to m; hence their total energies are as m to m'; in other words, the reflected train has received an accretion of energy equal to $1 - m'/m$ of the incident energy, which can only have come from mechanical work spent in pushing on the reflector with its velocity v. The opposing pressure is thus in numerical magnitude the fraction $\left(1 - \dfrac{m'}{m}\right)\dfrac{c}{v}$ of the density of the incident energy, which works out to be $\dfrac{c^2 - v^2}{c^2 + v^2}$ of the intensity of the total undulatory energy, direct and reflected, that is in front of the reflector.

When v is small compared with c, this agrees with Maxwell's law for the pressure of radiation. This case is also theoretically interesting, because in the application to æther-waves ξ is the displacement of the æther elements whose velocity $d\xi/dt$ represents the magnetic force; so that here we have an actual case in which this vector ξ, hitherto introduced only in the theoretical dynamics of electron-theory, is essential to a bare statement of the facts. Another remark here arises. It has been held that a beam of light is an irreversible agent, because the radiant pressure at the front of the beam has nothing to work against, and its work is therefore degraded. But suppose it had a reflector moving with its own velocity c to work against; our result shows that the pressure vanishes and no work is done. Thus that objection to the thermodynamic treatment of a single ray is not well founded.

This generalisation of the theory of radiant pressure to all kinds of undulatory motion is based on the conservation of the energy. It remains to consider the mechanical origin of the pressure. In the special case of an unlimited stretched cord carrying transverse waves the advancing reflector may be a lamina, through a small hole in which the cord passes without friction: the cord is straight on one side of the lamina, and inclined on the other side on account of the vibration; and it is easily shown that the resultant of the tensions on the two sides provides a force acting on the lamina which, when averaged, agrees with the general formula. In the case of an extended medium with advancing transverse waves, which are reflected directly, the origin of the pressure is not so obvious, because there is not an obvious mechanism for a reflector which would sweep the waves in front of it as it advances. In the æthereal case we can, however, on the basis of electron-theory, imagine a constitution for a reflector which will turn back the radiation on the same principle as a metallic mirror totally reflects Hertzian waves, and thus obtain an idea of how the force acts.

The case of direct incidence has here been treated for simplicity; that of oblique incidence easily follows; the expression for the pressure is reduced in the ratio of the square of the cosine of the angle of incidence. If we average up, after Boltzmann, for the natural radiation in an enclosure, which is incident equally at all angles, we find that the pressure exerted is one-third of the total density of radiant energy.

Adiabatics of an enclosed Mass of Radiation, and resulting General Laws.—Now consider an enclosure of volume V containing radiant energy travelling indifferently in all directions, and of total density E; and let its volume be shrunk by δV. This requires mechanical work $\frac{1}{3}\mathrm{E}\delta\mathrm{V}$, which is changed into radiant energy: thus

$$\mathrm{EV} + \tfrac{1}{3}\mathrm{E}\delta\mathrm{V} = (\mathrm{E} - \delta\mathrm{E})(\mathrm{V} - \delta\mathrm{V}),$$

where $\mathrm{E} - \delta\mathrm{E}$ is the new density at volume $\mathrm{V} - \delta\mathrm{V}$. This gives $\frac{4}{3}\mathrm{E}\delta\mathrm{V} = \mathrm{V}\delta\mathrm{E}$, or $\mathrm{E} \propto \mathrm{V}^{-\frac{4}{3}}$.

As already explained, if the original state has the constitution as regards wave-lengths corresponding to a temperature T, the new state must correspond to some other temperature $\mathrm{T} - \delta\mathrm{T}$. Thus we can gain work by absorbing the radiation into the working substance of a thermal engine at the one temperature, and extracting it at the other; as the process is reversible, we have by Carnot's principle

$$\tfrac{1}{3}\mathrm{E}\delta\mathrm{V}/\mathrm{EV} = -\delta\mathrm{T}/\mathrm{T},$$

so that $\mathrm{T} \propto \mathrm{V}^{-\frac{1}{3}}$.

Thus $\mathrm{E} \propto \mathrm{T}^4$, which is Stefan's law for the relation of the aggregate natural radiation to the temperature, established theoretically on these lines by Boltzmann.

Moreover, the Doppler principle has shown us that in the uniform shrinkage of a spherical enclosure the wave-lengths diminish as the linear dimensions, and therefore as $\mathrm{V}^{\frac{1}{3}}$, or inversely as T by the above result. Thus in the radiations at different temperatures, if the scale of wave-length is reduced inversely as the temperature the curves of constitution of the radiation become homologous, *i.e.*, their ordinates are all in the same ratio. This is Wien's theoretical law.

These relations show that the energy of the radiation corresponding to the temperature T, which lies between wave-lengths λ and $\lambda + \delta\lambda$, is of the form $\lambda^{-5} f(\lambda\mathrm{T})\delta\lambda$. The investigation, theoretical (Wien, Planck, Rayleigh, &c.) and experimental

[1] The present form of this argument arose out of some remarks contributed by Prof. FitzGerald, and by Mr. Alfred Walker of Bradford, to the discussion on this paper. Mr. Walker points out that by reflecting the radiation from a hot body, situated at the centre of a wheel, by a ring of oblique vanes around its circumference, and then reversing its path by direct reflexion from a ring of fixed vanes outside the wheel, so as to return it into the source, its pressure may be (theoretically) utilised to drive the wheel, and in time to get up a high speed if there is no load: the thermodynamic compensation in this very interesting arrangement lies in the lowering of the temperature of the part of the incident radiation that is not thus utilised.

(Lummer and Pringsheim, Paschen, &c.), of the form of this function f is perhaps the most fundamental and interesting problem now outstanding in the general theory of the relation of radiation to temperature. The theoretical relations on which this expression is founded have been shown to be in agreement with fact; and it appears that the form $c_1 e^{-c_2/\lambda T}$ fairly represents $f(\lambda T)$ over a wide range of temperature.[1] These relations have been derived, as usual, from a dynamical discussion of the aggregate intensity of radiation belonging to the temperature; it may be shown that the same results, but nothing in addition, will be gained by applying the same principles to each constituent of range $\delta\lambda$ by itself, assigning to each its own temperature.

SCIENTIFIC SERIALS.

American Journal of Mathematics, vol. xxii., No. 4.—Asymptotic evaluation of certain totient sums, by D. N. Lehmer, is an attempt to account for what seems to be a remarkable law, first observed in particular cases in 1895. It is thus stated: Consider any set s of k linear forms, $an+b_i (i=1 \ldots . k)$, all of which have the same modulus a, and where $[a, b_i]=1$, $[a, b]$ stands for the G.C. divisor of a and b. Consider, further, a function $\theta_s(x)$ such that $\theta_s(x)=1$ or 0, according as each of the prime divisors of x belongs to one of the forms of the set s or not. If, then, $\nu(x)$ denotes the number of distinct primes in x, we have

$$\lim_{N=\infty} \frac{\sum_{x=1}^{N} 2^{\nu(x)} \theta_s(x)}{N} = \text{constant}$$

The author's aim here is to prove this law where s is the set of linear forms belonging to a binary quadratic form. He also determines the constant in this case (pp. 293–335). Dr. E. H. Moore's paper concerning Klein's group of $(n+1)!$-ary collineations is a modification of a communication made to the American Mathematical Society, December 30, 1898. This short note is related to several papers by the author, amongst others with one communicated to the London Mathematical Society (December 1896, *see* vol. xxviii., p. 357). The closing paper (pp. 343–380), is one by H. E. Slaught, entitled "The Cross-ratio Group of 120 Quadratic Cremona Transformations of the Plane. Part i., Geometric representation." The group specially studied is a particular case, $n=5$ of the general cross-ratio group of order $n!$ Its consideration was undertaken as a dissertation at the University of Chicago at the suggestion and under the direction of Dr. Moore, and so is closely connected with the two papers referred to above. A few plates of figures are given at the end of the number, and also an obituary notice of Prof. T. Craig by Prof. S. Newcomb.

Symons's Monthly Meteorological Magazine, December.—Climatological table for the British Empire for the year 1899. This interesting summary of the climatological tables which have been published for a number of selected stations for the last quarter of a century shows that, generally speaking, the extreme values fall much to the same stations as usual. Adelaide records the maximum shade temperature, 113°·6 (in February). This temperature has only once been exceeded in these tables—viz. by 114°·2 in 1876. It had also the maximum temperature in the sun, 175°·7; this value is also unusual, the only higher reading being 180°, in 1882. It is also the driest station, the mean humidity being 59. The dampest station was Colombo, mean humidity 79; this station also records the highest mean temperature, 81°·9, and the greatest rainfall, 73·5 inches. The lowest temperature in the shade was −46°·5 at Winnipeg (in February); this station had also the greatest range in the year, 135°·9, the greatest mean daily range, 22°·3, and the lowest mean temperature, 34°·2. Mauritius was the most cloudy station—viz. 5·7; this extreme has several times been recorded at London, but in 1899 the cloud value was 5·6, only three out of the preceding forty years having been less cloudy.

[1] This might, however, be multiplied by $(T\lambda)^k$, and the experiments would hardly discriminate between the values zero (Wien), unity (Rayleigh), and one-half (Thiesen) for k; the latter value, which is entirely empirical, seems to fit best.

SOCIETIES AND ACADEMIES.

LONDON

Royal Society, December 6.—"On the Bacterial Disease of the Turnip (*Brassica napus*)." By M. C. Potter, M.A., F.L.S., Professor of Botany in the University of Durham College of Science, Newcastle-upon-Tyne. Communicated by Sir M. Foster, Sec. R.S.

This paper gives the results of an investigation into the cause of a special disease of the turnip crop. The disease was discernible in plants still growing in the fields, some roots being found which were quite rotten, the decaying portion being white with a highly offensive and peculiar smell. The most careful microscopic search failed to detect any trace of hyphæ of the higher fungi in the decaying mass, but only a swarming mass of bacteria. The tissues were completely disorganised, the cells separating from each other along the middle lamella; the cell-walls were soft, swollen and faintly striated; the protoplasm, too, had lost its natural colour and become slightly brown and contracted. The disease could be readily communicated to sound, growing roots by merely making a slight incision and inoculating the root at the injured surface.

After a long series of cultures a bacterium was isolated, and pure cultures obtained grown from a single individual, which produced all the symptoms of "white rot" when sown upon sterile blocks of living turnip. This bacterium rapidly liquefies gelatine, it is a short, motile rod with a single polar flagellum, and, adopting Migula's classification, has been described under the name of *Pseudomonas destructaus*. When growing in a living plant tissue or in nutrient solutions, a cytase is secreted; this was isolated by the well-known method of precipitation by alcohol, and has been shown to cause the dissolution of the cells and the softening and swelling of the cell-walls of the host.

The appearance of the diseased tissue could not be entirely explained by the action of the cytase. It was found that the boiled, filtered juice of a turnip, which had become rotten through the influence of a pure culture of *P. destructaus*, had a powerful toxic effect upon the living plant cell. This toxin proved to be oxalic acid. A reaction probably takes place between the calcium pectate of the middle lamella and the oxalic acid produced by the bacteria, the calcium pectate neutralising the oxalic acid and thus permitting the continued growth of the bacteria.

The action of this bacterium upon living plant tissues is similar to that of some of the parasitic fungi; in both cases the invading organism produces oxalic acid, which acts as a toxin to the protoplasm and, decomposing the calcium pectate, furthers the dissolution of the cells; and also there is the secretion of a cytase, which has a destructive action upon the cell-wall and intercellular substance. The question of the parasitism of the bacteria thus stands in these respects on the same platform as that of the fungi, and a complete homology is established between them.

From numerous observations in the fields it would appear that *P. destructaus* is always introduced at a wounded surface, and through the agency of slugs and larvæ.

"On the Tempering of Iron Hardened by Overstrain." By James Muir, B.Sc., B.A., Trinity College, Cambridge, 1851 Exhibition Research Scholar, Glasgow University. Communicated by Prof. Ewing, F.R.S.

It is well known that iron hardened by overstrain—for example, by permanent stretching—may have its original properties restored again by annealing—that is, by heating it above a definite high temperature and allowing it to cool slowly. Experiments described in the paper, of which this is an abstract, show, however, that if iron hardened by overstrain be raised to any temperature above 300° C., it may be partially softened in a manner analogous to the ordinary tempering or "letting down" of steel which has been hardened by quenching from a red heat. This tempering from a condition of hardness induced by overstrain, unlike ordinary tempering, is applicable not only to steel, but also to wrought iron, and possibly to other materials which can be hardened by overstrain and softened by annealing.

The experiments described in the paper were all carried out on rods of iron and steel about ⅜ths of an inch in diameter and 11 inches long, the elastic condition of the material being in all cases determined by means of tension tests, in which the hardness of the material was indicated by the position of the yield-point.

The method of overstraining and examining the materials employed was analogous to that described in a paper by the present author, "On the Recovery of Iron from Overstrain" (*Phil. Trans.*, A., vol. cxciii., 1899).

Experiments described in the paper, of which this is an abstract, showed that with mild steel which had been hardened by tensile overstrain until it could withstand a load of 50 tons per square inch without yielding, no appreciable softening was produced by heating the material to 300° C. A temperature of 350° C., however, lowered the yield-point to about 47 tons per square inch; 500°, 600° and 700° C. lowered the yield-point to about 40, 35 and 30 tons per square inch respectively.

It was further shown that the same temperature brought the yield-point to approximately the same stress, no matter what might be the original hardness of the specimen under test; and that the harder the material was made by tensile overstrain—that is, the higher the yield-point was raised by permanent stretching—the lower was the temperature which could be shown to produce a slight tempering effect.

The results ascribed above solely to temperature were found to be influenced to some extent by time. Thus it was found that by baking a hardened specimen for several hours at any temperature a greater effect was produced than by simply raising the specimen for a few minutes to that temperature. The effect of time was, however, small compared with that produced by increase of temperature.

All the tempering effects observed with steel were also obtained with Lowmoor iron. The hardening by overstrain and the tempering of soft Lowmoor iron only differed in detail from the analogous hardening and tempering of steel.

The iron and steel employed in this research were also examined when in various conditions of hardness by means of the microscope, and micro-photographs are reproduced in the paper. The ordinary methods of relief-polishing and of etching by dilute nitric acid were employed, and a new method of staining steel by rubbing with ordinary moistened cocoa was made use of and is described in the paper.

Geological Society, December 5.—J. J. H. Teall, F.R.S., President, in the chair.—On the Corallian rocks of St. Ives (Hunts) and Elsworth, by C. B. Wedd. (Communicated by permission of the Director-General of the Geological Survey.) Starting two and a half miles south-west of Elsworth, the author traces the Elsworth rock at intervals through Croxton, Yelling, Papworth Everard, &c., to Elsworth, and thence towards Fen Drayton and near Swavesey. The Oxford clay is found to the west of it, and the Ampthill clay to the east. Frequent fossil lists are given, and the character of the rock is described at the different exposures. Again, from Haughton Hall, west of St. Ives, the "St. Ives Rock" is traced through that town and towards Holywell.—The unconformity of the Upper (red) Coal Measures to the Middle (grey) Coal Measures of the Shropshire coalfields, and its bearing upon the extension of the latter under the Triassic rocks, by W. J. Clarke. The Upper Red Measures have a much greater extension in the Shropshire coalfields than the productive Measures below. In the Shrewsbury field they are the only Carboniferous rocks present, and rest on pre-Carboniferous rocks. When the sections of collieries at and near Madeley are plotted on the assumption that the base of the Upper Carboniferous rocks is horizontal, the Lower Measures are found to be bent into a syncline rising sharply to the north-north-west and more gently to the south-south-east. A second syncline, broader and deeper, extends from Stirchly towards Hadley, but the westerly rise is often hidden by the boundary-fault of the coalfield. This phenomenon is known locally as the "Symon Fault"; and, instead of taking Scott's view that it represents a hollow denuded in the Lower Coal Measures, the author considers it due to folding before late Carboniferous times. A third little syncline occurs at the Inett and Caughley. Similar phenomena are exhibited in the Forest of Wyre coalfield, where a series of unproductive measures come in between the Lower and Upper Coal Measures.—Bajocian and contiguous deposits in the northern Cotteswolds: the main hill-mass, by S. S. Buckman. After giving comparative sections at Cleeve, Leckhampton Hill, and Birdlip, to show the disappearance of three horizons at the second locality and five more at the third, the author interprets the absence of the beds as due to "pene-contemporaneous erosion" brought about by the elevation of rocks, due to small earth-movements along a main south-west to north-east axis and subsidiary axes north-west to south-east.

Entomological Society, December 5.—Mr. G. H. Verrall, President, in the chair.—Mr. Jacoby exhibited specimens of *Hypocephalus armatus* from Bahia and *Chrysomela salisburiensis*, a new species, from Mashonaland.—Mr. Bower exhibited a specimen of *Spilosoma montanum*, an Asiatic species, bred from a larva found beginning of September 1897, feeding on birch on a moor near Paisley. The larva hibernated and spun a cocoon the following spring, not feeding after hibernation. Moth bred June 2, 1898. The moor on which the larva was found is used by the Glasgow Corporation for rubbish, the supposition being that an ovum or larva had been introduced with the refuse matter.—Mr. McLachlan exhibited a female of a dragon-fly of the genus *Tetracanthagyna* from North Borneo, similar to *T. vittata*, McLach., but with a very broad ante-apical fascia on the wings, and with some asymmetrical markings. He said there might be a question as to the specific identity or otherwise of the insect. There was also the question as to whether the insect described by Mr. C. O. Waterhouse as *Gynacantha plagiata* in the *Transactions* for 1878 was specifically the same. Mr. Waterhouse was of opinion that his insect was distinct.—Mr. R. Adkin exhibited two aberrant male specimens of *Argynnis aglaia*. In one of them the basal two-thirds of all the wings were almost completely covered with black, and broad black streaks crossed the remaining third of the wings to the outer margin, following the venation. In the other specimen the peculiarity consisted in the presence of a greenish-white blotch on each of the wings on the left side, similar in character to the pale blotches not infrequently observed in *A. paphia*. Both specimens were taken near Brighton in July last, where the species was unusually abundant.—Papers were communicated on observations on some species of *Orina*, a genus of viviparous and ovo-viviparous beetles, by Mr. G. C. Champion and Dr. T. A. Chapman, reported by Dr. T. A. Chapman; illustrations of the sixth male ventral segment in seventeen species of *Osmia* of the *Adunca* group, with a note on the synonymy of three species, and descriptions of five which appear to be new, by the Rev. F. D. Morice, M.A.; and an obituary notice of the late Dr. Otto Staudinger, by Mr. H. J. Elwes, F.R.S.

Linnean Society, December 6.—Mr. F. D. Godman, F.R.S., Vice-President, in the chair.—Dr. A. B. Rendle exhibited specimens, including leaves and fruit, of Grasswrack (*Zostera marina*, L.) recently found by Capt. H. P. Deasy near Yepal Ungar, in the Kwen Lun mountains, at an altitude of 16,500 feet. The plants were not growing in this remarkable locality, but were preserved in a bed 10 to 12 feet thick on top of and interspersed with which were strata of blue clay. The broken leaves and sheaths of which the specimens consisted were dry and brittle, but showed no alteration, the internal structure being as perfect as in the fresh plant. As the country is geologically unknown, it is impossible to estimate the age of the deposit. It probably formed the bed of a salt-lake. There is one in the neighbourhood; and Capt. Deasy is of opinion that the whole district formed at one time a large salt-lake. The specimens were very dusty, but microscopic examination of the dust revealed nothing beyond particles of sand and a few small brown objects, apparently spores of some kind. Capt. Deasy states that he saw similar growths in a lake in the same district, but was unable to procure specimens. This occurrence of *Zostera marina* in the heart of the Asiatic continent, and at so great an elevation, is of special interest. The plant, so far as known, is purely marine, occurring plentifully on our own coasts and throughout Europe, on the Atlantic shores of North America, and in North-east Asia. It has not previously been recorded from an inland lake, though an allied species, *Zostera nana*, L., occurs in the Caspian. Whether its existence in the Kwen Lun range has any relation to the Tertiary marine deposits which connect the Mediterranean area with the Himalayas is matter for conjecture. There seems to be some evidence for the existence of *Zostera* in Upper Cretaceous and Tertiary times; at any rate several species have been described from fossils resembling the rhizome of the plant, found in Central European beds. Dr. Rendle also showed a specimen of another marine monocotyledonous plant, *Halophila stipulacea*, Asch., from Tuticorin in Southern India, sent by Mr. Edgar Thurston. This species is not included in the "Flora of British India," nor in Trimen's "Ceylon Flora," a plant found by Dr. Harvey at Trincomalee, and thus determined by Thwaites, being assigned to the commoner *H. ovata*, Gaud. *H. stipulacea* occurs in the Red Sea, the Mascarene Islands, and Rodriguez.—The Rev. John Gerard exhibited some abnormally large shells of the swan mussel, *Ano-*

donta cygnea, forwarded from Claughton, Garstang, Lancashire, by Mr. W. Fitzherbert Brockholes. The three largest of these measured 8·75 inches, 8 inches and 7·5 inches in width, these measurements being considerably in excess of those given in the text-books, and of the examples figured as *Mytilus cygneus* in *Trans.* Linn. Soc. vol. viii. pl. 3, p. 109, and as *Mytilus stagnalis* (from Kew Gardens) in Sowerby's "British Miscellany," vol. i. pl. xvi. p. 33. It was stated that amongst other specimens found in the pond at Claughton, when drained, there was one of nine inches, twenty-eight measuring from 8 to 9 inches, and about a hundred of 7 to 8 inches.—Mr. F. Chapman read a paper on some new foraminifera from Funafuti, on which some remarks were made by Mr. Sherborne.—Mr. H. Groves, on behalf of Mr. G. C. Druce, communicated a paper entitled, A revision of the British thrifts (*Statice* and *Armeria*), in which he attempted a rectification of the synonymy, and discussed the value of the pubescence on the ribs of the calyx as a distinguishing character.

Royal Meteorological Society, December 19.—Dr. C. Theodore Williams, President, in the chair.—Mr. H. Mellish read a paper on the seasonal rainfall of the British Isles, which he illustrated with a number of lantern slides. He discussed the rainfall returns from 210 stations for the twenty-five years 1866-90, and calculated the percentage of the mean annual rainfall for each season. In winter the largest percentages of rainfall are found, as a rule, at the wet stations, and the smallest at the dry ones. Spring is everywhere the driest quarter, and the percentages are very uniform over the country, rather larger in the east then in the west. In summer the highest percentages are found in the dry districts, and the lowest in the wet ones. As the spring is everywhere dry, so is the autumn everywhere wet, and there is little difference in the proportion of the annual total which falls in the different districts. As regards the relation between the amount of rain which falls in the wettest and driest month at any station, it seems to be generally the case that the range is larger for wet stations than for dry ones. In wet districts rather more than twice as much rain falls, on the average, in the wettest month as in the driest, and in dry districts rather less than twice.

EDINBURGH.

Mathematical Society, December 14.—Mr. J. W. Butters, President, in the chair.—Dr. Third read a paper on triangles triply in perspective, and a paper on four circles touching a common circle, by Prof. Allardice, was communicated to the meeting by Mr. George Duthie.

CAPE TOWN.

South African Philosophical Society, November 28.—M. L. Péringuey, President, in the chair.—The Secretary read a paper by Dr. R. Broom, of Pearston, on the leg and toe bones of *Ptychosiagum*. Dr. Broom described a tibia and fibula, together with the greater part of two toes and a couple of carpal bones, found near Colesberg in association with the skull of *Ptychosiagum Murrayi* and presented to the Eastern Province Naturalists' Society by Mr. Leslie, of Port Elizabeth. The structure of the leg and toes confirm the view, based on the portion of the nostrils, that Ptychosiagum was an aquatic form.—Dr. J. D. F. Gilchrist read a paper entitled "The History of the Local Names of Cape Fishes." The object of the paper was to clear up certain difficulties caused by the use of different names and review their historical origin and development from a philological point of view. A list of over 200 names was procured, many of which were synonyms. These were arranged alphabetically, the synonyms grouped together and followed by the scientific name where possible. Traces of East Indian, French and Portuguese elements were found in the nomenclature, the most prominent being, however, Dutch and English.

NEW SOUTH WALES.

Linnean Society, October 31.—Mr. Henry Deane, Vice-President, in the chair.—Tasmanian land planarians: descriptions of new species, &c., by Thos. Steel.—Contributions to a knowledge of the Australian flora, Part iii., by R. T. Baker. A number of species of phanerogams and fungi not previously known to occur in New South Wales are recorded, as well as additional localities for already recorded New South Wales species.—Studies in Australian entomology: No. x., description of a new tiger-beetle from Western Australia, by Thomas G. Sloane.—Description of a specimen of kerosene shale from Megalong Valley, N.S.W., by Prof. C. E. Bertrand, Lille. A detailed description of the microscopic and macroscopic characters of a kerosene shale from Megalong are given. The shale belongs to the same type as the shales from Mount Victoria and Blackheath containing the alga, *Reinschia australis*. It is noteworthy, however, for the excellent state of preservation of the remains of the minute fossil forms. Associated with the alga are pollen grains and spores. The author has calculated that there are 16,830 thalli of *Reinschia* in a cubic millimetre of the shale.—On the "clouding" of white wine, by R. Greig Smith. A variety of chablis becomes clouded and turbid soon after bottling, which renders the wine commercially useless. The cause has been traced to an acetic-acid-forming bacterium which grows only upon wine and yeast-derived fluids. By inoculation of the pure organism into sterile wine, the trouble was reproduced. The remedy consists in pasteurising the wine.—On some new species of Eucalyptus, by R. T. Baker.

ST. LOUIS.

Academy of Science, December 3.—Mr. William H. Roever, of Washington University, read a paper on brilliant points and loci of brilliant points. The paper gave the analytical conditions which define the brilliant point of a surface, the brilliant point of a space curve, the brilliant point of a plane curve and the brilliant point in space of two dimensions, when the source of light is such that the incident rays are normal to a given surface and the recipient is such that the reflected rays are normal to another given surface. Formulæ were given for the important special case in which the source and recipient are points. The paper also contained a general method for finding the equation of the locus of the brilliant points of a moving or variable surface or curve, together with a number of applications. Such loci may often be perceived when an illuminated polished surface is rapidly moved, as when a wheel with a polished spoke is rapidly rotated. Another interesting example in loci of brilliant points is that of a circular saw which has been polished with emery in a lathe and thus received a great number of concentric circular scratches. The locus of the brilliant points of this family of scratches was shown in this paper to be a curve of the fourth degree. In the special case when the point source of light and the eye of the observer (the point recipient) are in a plane through the axis of the saw, the curve degenerates into a circle and two coincident straight lines.

THURSDAY, JANUARY 3, 1901.

THE NEW CENTURY.

SCIENCE is cosmopolitan. Electricity abolishes time and envelops both hemispheres with a new idea as soon as it has emerged from the brain of the Thinker. Mechanics, by its space-annihilating power, has reduced the surface of the planet to such an extent that the human race now possesses the advantage of dwelling, as it were, on a tiny satellite. Both these agencies, then, combine to facilitate a rapid exchange of new ideas and commodities, as well as of those who are interested in them in whatever capacity.

These considerations indicate some of the most momentous changes which have occurred in the world's history since the last century dawned.

How have they been brought about? M. Maurice Lévy, in one of those allocations—always so admirable in thought and style—pronounced by the President of the French Academy of Sciences at the annual public meeting held each December, answered the question for us last month.

"Let us never forget that if applied mechanics has arrived to-day at such marvellous results, if we can now calculate beforehand the parts of the most complex machines, it is because long ago the shepherds of Chaldea and Judea observed the stars; because Hipparchus combined their observations with his own and handed them down to us; because Tycho-Brahe made better ones; because two thousand years ago a great geometer, Appolonius of Perga, wrote a treatise on conic sections, regarded for many centuries as useless; because the genius of Kepler, utilising this admirable work and the observations of Tycho-Brahe, gave us those sublime laws which themselves have been considered useless by the utilitarians; and, finally, because Newton discovered the law of universal gravitation."

From this discovery of Newton, M. Lévy points out, first came the study of Celestial Mechanics, from which was derived later General Mechanics, from which again, later still, Industrial Mechanics, which are now applied every day, has taken its origin. He adds:

"It is well to impress the fact that Industrial Mechanics has come down from heaven, upon the utilitarians; upon those who appreciate science only so far as it can be immediately profitable to them; who are always complaining that too much is taught at school, and who regard as superfluous everything they cannot find in a formulary, manual or aid to memory."

All our progress, then, if we accept the view to which M. Maurice Lévy has given expression, has come from the study of what was useless at the time it was studied. There is no doubt that this view is correct, and that future developments, probably as momentous as those to which we have already referred, will in the future come to us from the same source.

To study the useless, therefore, is as important as to apply the useful, from a cosmopolitan point of view; and all wise governments and institutions should use their most strenuous efforts to aid the first endeavour, the second can very well take care of itself.

There can be no question that the progress of science and of the applications of science to industry will go on in a geometrical ratio, and that eventually every country will benefit by this advance; but if we quit the cosmopolitan point of view and endeavour to form an idea of the results of this advance on any country in particular, another set of considerations comes in.

Our Empire, as it exists at present, and our great national wealth, are the results of the sea-training and prowess of her sons and of the stores of natural wealth in the shape of coal and iron which the first appliers of mechanics found to their hand. The output and first user of coal and iron depended upon the applications of mechanics, and the first user of all these combined enabled us to flood the markets of the world, and for years Britain was the Tubal Cain among the nations. Not only had we a monopoly of export, but so high an authority as Sir Andrew Noble acknowledges that, fifty years ago, British machinery was immeasurably superior to any other. But even this statement does not exhaust all our then advantages. Because we were the great producers we became the great carriers of the world; hence the supremacy of our mercantile marine, and, flowing from this, our command of the sea. At that time Germany did not exist as a united nation, France was mainly agricultural, and the United States were engaged in developing their enormous and almost unpopulated territories.

But what has happened since? As we have said, science is cosmopolitan, and the levelling effect of this has been that the *material* advantages we possessed in the first instance have disappeared. Other countries, chiefly those we have named, have now their coal and iron and applications of science as well as ourselves.

First among these applications at the beginning of the last century came steam locomotion, the gift to the world of a former "instrument maker to the University of Glasgow," and from the work done on the Forth and Clyde Canal in 1802 have sprung all the navies and railways of the world.

For traction purposes steam is now giving way to electricity; but how different is the *rôle* that Britain is playing at the beginning of the new century compared with that she filled at the beginning of the old one. We import instead of exporting. The chief London electric railway is American, American coal is producing gas to light the streets of the Metropolis, American cars are now found on our English trains, which on some lines are drawn by American locomotives. British applications to facilitate locomotion, therefore, have ceased to be paramount, and at the same time we no longer occupy the proud position of being the only nation of shopkeepers.

Were this all, it would be abundantly clear that our old supremacy must cease, and from no fault of our own, as it is but a direct consequence of the general progress of science, which includes the facilitating of intercommunications. But, unfortunately, it is not all.

At a time when our ancient universities occupied no higher level than that, according to Matthew Arnold, of "hauts Lycées," and when there was little or no attempt at

educating the large majority of the population, Prussia, which, with the rest of the German States, had profited by Luther's appeal in favour of the education of the people, had occupied herself, crushed though she was after Jena, with the founding of universities and with the highest education; while live seats of learning in great numbers were being founded in the United States. The beginning of the new century, then, finds us in a position which every day differs more and more from that occupied by us in the old one, for not only are our natural resources relatively reduced in value, but our intellectual resources are not sufficiently superior to those of other nations to enable us to retain our old position by force of brains.

But even this statement does not truly paint the situation. From time to time since this journal was started in 1869, it has been our duty to insist upon our relative deficiencies in regard to the advancement of science and the higher scientific instruction. Thus, in the very first volume of NATURE, the absence here of the great facilities and encouragement given in Germany to these matters was clearly indicated. As an early instance of the result of this state of things we may refer to Mr. Perkin's account, in 1885,[1] of the migration of the coal-tar industry to Germany. In later years ample proof has been adduced that in many directions the present British intellectual equipment is not only not superior, but actually inferior to that of other countries, and none too soon the matter is engaging attention in the daily press. Within the last week the *Times*, *Daily Mail* and *Pall Mall Gazette* have called special attention to the reasons which may be assigned for this new and alarming state of things; a writer in the *Fortnightly* has gone so far as to ask, "Will England last the Century?" while Sir Henry Roscoe has expressed his opinions in a letter to the *Times* as follows:—

"There can be no manner of doubt that a crisis in our national well-being has already been reached. The news brought to us from all quarters proves that our industrial and commercial prosperity is being rapidly undermined. The cry that we are being outbid on all sides by Germany and America is no new one, but it becomes louder and louder every day, and now it is admitted by all those best qualified to judge that, unless some drastic steps are taken to strengthen our educational position in the direction long ago taken up by our competitors, we stand to lose, not merely our industrial supremacy, but the bulk of our foreign trade. . . . The only policy at this time is to strain every nerve to place the country educationally on a level with its neighbours. No effort, no expenditure, is too great to secure this result, and unless our leaders, both in statecraft and in industry, are quickly aroused to the critical condition of our national affairs in this respect, and determine at once to set our house in order, our children and grandchildren may see England sink to the level of a third-rate Power; for upon education, the basis of industry and commerce, the greatness of our country depends."

We must confess that when we come to consider the panaceas suggested by these writers we find much more vagueness than might be expected, and some suggestions which are entirely beside the mark.

Thus we are told that now our Colonies are being more closely united to us, we may rest and be thankful; that American industry depends for its success upon the extreme youth of those who are at the head of affairs. Education is referred to as if there were no differences in the methods employed, and finally a newly-developed sloth is suggested as the origin of the apparent decadence of the most athletic nation in the world.

The question arises, Is there no scientific method open to us to get at the real origin of the causes which have produced the present anxiety?

M. Maurice Lévy, in his allocation, did England the honour to point out how large a share Newton had in founding the industries on which our commercial greatness in the last century was based. It seems to us to be our duty, at the beginning of the new century, to suggest that at this critical time it would be criminal to neglect the labours of another great Englishman—Darwin—which may be appealed to to help us to see what has gone wrong and to forecast what the future has in store for us if we apply the suggested remedies or if we neglect them. In this we possess an advantage over our forerunners. Those labours have shown the working of an inexorable law which applies exactly to the conditions under which we find ourselves.

The enormous and unprecedented progress in science during the last century has brought about a perfectly new state of things, in which the "struggle for existence" which Darwin studied in relation to organic forms is now seen, for the first time, to apply to organised communities, not when at war with each other, but when engaged in peaceful commercial strife. It is a struggle in which the fittest to survive is no longer indicated by his valour and muscle and powers of endurance, but by those qualities in which the most successful differs most from the rest. We must accept the conclusion that, with material outfits now much more equally distributed for this struggle for existence, if Britain be at a disadvantage in relation to any other nation with regard to these qualities, it must go under if such a condition of things is allowed to go on. If this appeal to a natural law leads to such a dire conclusion, it is the duty of every Briton, from the highest to the lowest, to see to it that some efficient remedy be applied without delay.

It follows from what has already been stated that we need not look for these national differences among natural products for the reason that, day by day, such differences are being levelled by the present ease and rapidity of intercommunication.

We do not think that the differences will be found in any very great degree in our primary and technical instruction as it is going on to-day.

If we regard our primary, secondary and higher education, it must be acknowledged that great improvements have been carried out during the last quarter of a century. The establishment of new universities, adapted to the present conditions of civilisation, in several great centres and the promise of more, has clearly shown that, in the opinion of our most important mercantile communities, strong measures are necessary, and that they are prepared to make great pecuniary sacrifices to carry them out. Still, the facts show that what has already been done

[1] NATURE, vol. xxxii. p. 343.

is not sufficient, and that we must do more in these directions; but the present difference in these respects is not entirely sufficient to account for the present condition of things.

Continuing our process of exclusion we finally arrive at the possibility that the present superiority of our competitors depends as much upon Liebig's introduction of practical scientific work and research into the general higher education as did our former supremacy upon Watt's introduction of the steam engine. Voltaire said, "On étudie les livres en attendant qu'on étudie les hommes." The proper study of Science gives us a third term, the study of things and laws in action; a study in which the eye and hand and brain must work together to produce the scientific spirit or properly organised common sense.

The Scientific spirit existed among our European competitors much more generally than it did with us long before Liebig, and it was utilised over a far wider field of knowledge; but from Liebig's time it has existed among them as the dominant factor in Industry and Commerce, and the closer union between Science and Industry in other countries is, we believe, the true origin of the present difference between them and our own.

Here, we tried to start chemical industries by employing chemists, as Mr. Perkin has told us, at "bricklayers' wages." In Germany they are now carried on by scores, in one case a hundred, of the best trained chemists the country can produce, in research laboratories attached to all the great works. At this moment German artificial indigo threatens to replace the natural product in all the markets of the world as a result of these scientific industrial methods. So soon as Science was acknowledged to be the most important commercial factor, the Reichsanstalt was established by the Government at a cost of 200,000*l*., and a yearly expenditure of 15,000*l*. to weld science and industry more closely together. An American professor thus summarises the results:

"The results have already justified, in a remarkable manner, all the expenditure of labour and money. The renown in exact scientific measurements formerly possessed by France and England has now largely been transferred to Germany. Formerly scientific workers in the United States looked to England for exact standards, especially in the department of electricity, now they go to Germany." And again, "Germany is rapidly moving toward industrial supremacy in Europe. One of the most potent factors in this notable advance is the perfected alliance between science and commerce existing in Germany. Science has come to be regarded there as a commercial factor. If England is losing her supremacy in manufactures and in commerce, as many claim, it is because of English conservatism, and the failure to utilise to the fullest extent the lessons taught by science."

Britain, of course, is the country in which such an institution ought to have been established more than half a century ago. We are now compelled to imitate it; but the new institution which, before long, may be instituted is on such a microscopic scale that its utility in the present struggle is more than doubtful.

The next conclusion the appeal to the law provides us with is that the improved scientific instruction of those engaged in Industry is not the only line along which our defences must be strengthened. The scientific spirit must be applied as generally in England as elsewhere.

The increasing complexity of industrial and national life requires a closer adjustment of means to ends, and this can only be attained by those who have had education on a scientific basis, and have therefore acquired the scientific habit. In this way only can we lift the whole standard of our national life to a higher plane, and weld the various national activities together.

We must have a profound change of front on the part of the Ministry and the personnel of Government departments, only very few of whom have had any scientific education and who at present regard all scientific questions with apathy, on the ground, perhaps, that in their opinion the Nation has no direct concern with them. This feeling may be strengthened by the fact that at present, while the laws of the realm are well looked after by the most highly paid servants of the State, the laws of Nature are left without anybody to form a court of appeal in difficult questions. It is true that to fill this gap our men of science are always ready, when called upon, to spend time and energy on affording, gratis, to the Government advice on any questions which may be submitted to them; but because this advice costs nothing its value is, perhaps, estimated by what it costs.

Our rulers must recognise that, in virtue of the law to which reference has been made, it will not do to confine their energies and the national expenditure, so largely as they do now, to matters relating to the Navy and Army, the functions of which are to protect our world-wide Empire at present well worth conquering, our industries, and our argosies on every sea—products, all of them, of our old scientific and therefore commercial supremacy.

Several obvious corollaries from the law in question indicate very clearly the proper course to pursue, in our own case to retain our position, in the case of our competitors to improve their own in relation to us, and therefore at our expense. There are many signs that our competitors, at all events, have faced this problem and are working on true scientific lines; of this the heavy subsidy of the German mercantile marine may be given as one instance out of many, and here, indeed, we are brought face to face with the consideration that the scientific outlook should really be as important to those in charge of the Nation's future well-being as that concerned with international politics.

If the other nations, by their scientific activity, increase their commerce and therefore their commercial fleets, their national fleets must be increased also. Our present policy with regard to our fleet is well established, so that we are committed to its continuous and well-defined increase, while it seems to be the duty of no Government department to look after the scientific advances which are the only bases of the commerce which is to provide for the constantly increasing expenditure. So that if, in the future, a constantly reduced commerce and commercial marine, and therefore reduced

national income, are in store for us, we shall have, because of this condition of things, to face a constantly increased expenditure upon our fleet.

These considerations are only typical of others which are well worth considering at the present juncture by men possessing the scientific spirit. What is the best way of utilising the combined forces of the Empire, in times of peace, under the present conditions? It is clear that no merely sentimental bonds will be sufficient. We may add that peaceful conflicts between industrial peoples are not alone in question.

With regard to preparation for war, history has already taught us much. Of two competitors, if one be fully armed both for offence and defence, and the other is not, there is no doubt as to what will happen. That nation will be the best off which utilises the greatest number of its citizens both for war and peace. A large standing army in times of peace is a clear indication that the scientific spirit has not been sufficiently applied to the problem, and it is to be hoped that now the future of the Nation is being discussed, the attempts to put our house in order will be made on scientific lines.

EDITOR.

RECENT ADVANCES IN THE CHEMISTRY OF THE PROTEIDS.

Chemie der Eiweisskörper. Von Dr. Otto Cohnheim. Pp. x + 315. (Braunschweig: F. Vieweg und Sohn, 1900.)

SINCE the publication of Drechsel's article on proteids in Ladenburg's Encyclopædia, no complete account of the chemistry of the proteids has appeared. The accounts given in the best known text-books of physiological chemistry are necessarily brief and incomplete. Dr. Cohnheim's book is therefore a very welcome addition to the literature of physiological chemistry, giving, as it does, a detailed account of the present state of knowledge with regard to the proteids.

The book is divided into a general and a special part. The first deals with the physical and chemical properties of the proteids, then with the products of their decomposition, and finally discusses their structure and classification. In the second part, the characteristics of the different forms of proteids are considered in detail.

In reviewing the book as a whole, it is impossible to do more than emphasise those features in which it shows a distinct advance as compared with its predecessors.

The chief characteristics which distinguish the proteids as a sharply limited class of organic compounds are the following. They contain the elements carbon, hydrogen, oxygen, nitrogen and, as a rule, sulphur in fairly constant proportions, and although their constitution is as yet unknown, the similarity in their chemical behaviour is so great that they may all be regarded as having a common chemical structure. Provisionally they may be divided into three groups, the native simple proteids, the compound proteids—in which a simple proteid is united to some other organic body—and the earlier decomposition products which still retain, in large measure, the chemical properties of the proteids from which they have been derived. The compound proteids may contain, in addition to the elements already mentioned, phosphorus and iron.

Their properties may be divided into physical and chemical. Taking the former first, the author selects, as their most characteristic property, the tendency of all native proteids to pass readily out of solution in the form of a more or less permanently insoluble precipitate or coagulum.

Means otherwise chemically indifferent, such as mechanical agitation of their solutions, contact with porous substances, or evaporation of part of the water of solution, result in the separation of a flocculent precipitate, which, on microscopic examination, is found to consist of minute particles tending to cohere so as to form membranes or threads of coagulated proteid. It is this property of proteids which explains their indiffusibility and the difficulty with which they undergo crystallisation.

Chief amongst the physical agents which produce this change is heat. To the subject of coagulation by heat a special chapter is therefore devoted. In the presence of a fixed quantity of neutral salt of the metals of the alkalies, and a very faint acid reaction, the temperature of coagulation is fairly constant for each native proteid, and has proved of considerable value in their separation and classification. A variation in the quantity or nature of the salt used alters the temperature of coagulation of any given proteid. Further, the proteid that separates out from a faintly acid solution carries with it some of the acid, so that the solution after coagulation is found to be less acid than before, or may even be neutral. The latter fact renders the coagulation of proteids by heat specially liable to fallacy as a method for their separation. The part played by the neutral salt in heat coagulation is still doubtful. Most observers have found that proteids, in solutions freed as far as possible from salts by dialysis, do not coagulate on heating; but the addition of a small quantity of neutral salt to the previously heated solution results in the separation of a coagulum. Cohnheim, therefore, regards coagulation by heat as invariably associated with the formation of an acid albumin insoluble in salt solution; but soluble in the least excess of the acid used. The evidence, however, on the influence exerted by neutral salts on the temperature of coagulation is conflicting. There is evidence that, in some cases, a proteid solution, freed as far as possible from salts by means of dialysis, coagulates at a lower temperature than when a small quantity of neutral salt is present. By means of dialysis alone it has not, as yet, been found possible to obtain a native proteid free from ash, so that the influence of heat upon a native proteid solution free from mineral matter has not yet been studied.

The next section of the book deals with the methods used for salting out proteids, and contains a complete account of the relative value of various salts as precipitants. Of all salts of the metals of the alkalies and alkaline earths, ammonium sulphate has the greatest precipitating power. Saturation with it precipitates all the native proteids from solution, and, with the exception of peptone, all the products of peptic or tryptic digestion still retaining proteid characters. Its precipitating power is increased by the addition of dilute acids, and, in the

case of some of the products of digestion, the addition of an acid is found necessary for precipitation. In neutral solution, the concentration of salt necessary for precipitation is found to vary with the nature of the proteid. Hofmeister and others have ascertained for a number of proteids the limits of concentration of ammonium sulphate necessary for their precipitation, and upon this basis have founded the method of fractional precipitation. By this means it has been found possible to separate from a mixture of proteids fairly well defined chemical individuals.

Another method of separation that is being used to an increasing extent is that of crystallisation ; but, unfortunately, its application is somewhat restricted. Dr. Cohnheim has, probably for this reason, relegated the subject to the second part of his book. Egg-albumin, serum-albumin and lactalbumin are the only simple proteids of animal origin that have been obtained in a crystalline form. The first method devised is due to Hofmeister. He succeeded in obtaining crystals of egg-albumin from egg-white by first of all precipitating the globulin by half saturation with ammonium sulphate. When the filtrate was allowed to slowly evaporate, egg-albumin gradually separated out in the form of minute globules. By re-dissolving the globules and repeating the process, he ultimately obtained well-defined crystals of egg-albumin which were purified by recrystallisation.

A much simpler and more satisfactory method has been discovered by Hopkins and Pinkus. After half saturating the egg-white with ammonium sulphate some ammonia is given off, and it was found that, after neutralising the ammonia with dilute acetic acid and then adding sufficient excess of acid to produce a slight precipitate of proteid, the crystallisation of the egg-albumin was rendered much more rapid. The crystallisation induced by this method occurs in closed vessels without any concentration of the solution, and therefore without the risk of the separation of ammonium sulphate crystals along with the proteid ones. Fifth normal sulphuric acid has been also used, instead of acetic acid, with similar results. Up to the present few attempts have been made to separate different forms of albumin by means of fractional crystallisation ; but, since the work of Hopkins and others has simplified the process, one may hope for farther applications of the method in the future. The method may possibly be found capable of extension to forms of proteid other than the albumins.

In the succeeding chapter an account is given of the average composition of the simple proteids, and of the methods used in determining their molecular weight. None of the physical methods that have as yet been tested are sufficiently delicate to permit an accurate estimation of the molecular weight of the proteids. Measurements of the lowering of the freezing point and of the osmotic pressure have been tried ; but are very difficult to apply on account of the practical impossibility of obtaining proteid free from admixture with inorganic substances. A full account is given of the chemical methods, which yield more trustworthy results. Although the risks of fallacy are numerous, the results yielded by the chemical methods in many cases render it possible to give at least a minimum value for the molecular weight.

The author passes in the next place to a consideration of the chemical characters of proteids. They have the character of potential acids or bases, according to the alkaline or acid reaction of the solution. When one compares the different forms of proteid, one finds that either the basic or acid character may predominate. The simplest forms of proteids, such as the protamines and histones, have a well marked basic reaction. The greater number of the remaining simple proteids play the part of base or acid with almost equal readiness. As a rule, however, the acid character is more emphasised. Simple proteids have, as acids, a distinctly dibasic character. The compound proteids, for example, nucleoproteids, nucleoalbumins and glycoproteids, have a still more marked acid character ; but in their case the acid reaction is mainly due to another organic group that has united with a molecule of a simple proteid.

In addition to these salt-like compounds of albumin, one finds compounds with inorganic material, for example, the halogens or iron, in which the halogen or iron is present in a more stable organic combination, and not as an ion. Some of these have been prepared artificially ; others by means of vital processes. It appears certain that the organism is capable of forming a stable organic compound of proteid containing iodine in which the character of iodine as an ion is lost, even when the only substances in the food given contained iodine in an inorganic form.

The chief characteristic reactions of proteids next considered may be divided into precipitation and colour reactions. In virtue of their basic character, most proteids, when in the presence of an acid, may be precipitated by the precipitants of the alkaloids. As acids, proteids form insoluble salts with most of the heavy metals. On these facts, methods have been founded for the estimation of the basic or acid equivalents of various proteids. Cohnheim illustrates this by the following example. The hydrochloric acid salt of a proteid and calcium phosphomolybdate = the insoluble compound of the proteid with phosphomolybdic acid and calcium chloride. Since the hydrochloric acid salt of a proteid reacts as an acid to phenolphthalein while calcium chloride is neutral, the diminution of acidity after precipitation can serve as a measure of the basic equivalent of the proteid. The more basic forms of proteid, for example, histones and protamines, are precipitable by reagents for the alkaloids from neutral or even alkaline solutions.

The colour reactions of the proteids are dependent on the presence of certain organic radicles in the proteid molecule, and owe their importance to the light which they throw upon the chemical structure of the proteids. The failure or success of any given colour reaction indicates the absence or presence of the corresponding organic group in the proteid molecule. By a careful study of the colour reactions and of the simpler decomposition products of the proteids, it may be possible in the future to subdivide the different proteids into structurally distinct classes, and thus to establish a classification of the proteids upon a chemical basis.

The most important of the colour reactions is the biuret reaction. The conditions necessary for its occurrence have been very fully studied by Schiff. It is given by all chemical bodies containing two $CONH_2$ groups united

either directly or by means of an atom of carbon or nitrogen. The oxygen in the $CONH_2$ groups may be substituted for sulphur without interference with the reaction. As all proteids give this reaction, the proteid molecule must contain at least one organic group corresponding to one of the three forms described by Schiff.

The simplest forms of proteid, the protamines, and their digestive products the protones, give the biuret reaction, but none of the other colour reactions of the proteids.

Kossel gives $(C_{30}H_{57}N_{17}O_6)_n$ as the formula of clupein, one of the most thoroughly examined protamines. On further hydrolytic decomposition, the protones yield the hexone bases, arginin, $C_6H_{14}N_4O_2$ (guanidin-α-amido-propionic acid), and histidin, $C_6H_9N_3O_2$, a base of unknown constitution. The hexone bases appear to be the only primary products of decomposition. Their relative proportion varies considerably, according to the particular protamine examined. None of these hexone bases give the biuret reaction, nor does any other one of the products of decomposition of the proteids of known constitution. The biuret reaction is therefore in general use as a criterion, distinguishing the proteid bodies in the widest sense from their simpler products of decomposition.

The protamines are chemically and, as the work of Miescher and others has shown, probably genetically the precursors of the more complex forms of proteid. The basic organic groups in proteid which give the biuret reaction are also the most resistant to the action of digestive enzymes, and make up the greater part of Kühne's so-called anti-group. Starting from these facts, Kossel has suggested that the nucleus of the proteid molecule has a structure resembling that of protamine. To this nucleus other organic groups become added, so as to form proteid bodies of more complex structure, and he has suggested that upon these facts might be founded a chemical classification of the different proteids. The steps of the synthesis of proteids within the organisms of plants and animals are still, however, too vaguely known to admit of such a classification. Further, Kossel's conjecture has not proved to agree completely with the facts, proteids being known which give a well-marked biuret reaction, although, upon hydrolytic decomposition, they yield a relatively small quantity of the hexone bases. One may therefore conclude that proteid bodies giving the biuret reaction do not always contain a protamine nucleus in the sense originally suggested by Kossel; but the evidence that a group of basic character giving the biuret reaction forms the nucleus of the proteid molecule is fairly conclusive. The biuret group may belong to any of the types defined by Schiff, and there is evidence that several biuret groups are present in the more complex proteids. One of these groups contains a relatively large percentage of sulphur.

The majority of the other colour reactions of the proteids are dependent on the presence of an aromatic or of a carbohydrate radicle. Millon's reaction is given only by bodies which contain a benzene group in which one atom of hydrogen has been substituted for hydroxyl. The xanthoproteic reaction indicates the presence of a benzene group.

The colour reactions resulting from the presence of a carbohydrate radicle may be grouped together as furfurol reactions. On heating with mineral acids many of the proteids yield furfurol, which may be detected by the colour reactions which it gives with α-naphthol and thymol. In those proteids which contain both an aromatic and a carbohydrate group, the addition of thymol or α-naphthol is unnecessary, a colour reaction being obtained by the action of the furfurol on an aromatic radicle split off from the proteid itself. The chief reactions which indicate the presence of a carbohydrate as well as an aromatic group are those of Liebermann and Adamkiewicz.

There are a number of other colour reactions which, as yet, have not been so carefully studied as those already mentioned. Of these the most important are Petri's diazo-reaction, which is also given by the hexoses and is, therefore, probably dependent upon a carbohydrate group, Würster's quinone reaction, which appears to depend on the presence of the tyrosine group in proteid, and Reichl's reaction with benzaldehyde, which is also given by indol and scatol. Dr. Cohnheim has omitted the discussion of the latter reactions, possibly because their significance has not been sufficiently determined.

Within the limits of a review it would be impossible to discuss the next section of the book, which deals with the simpler products of the decomposition of proteids resulting from the action of various hydrolytic agents, concluding with a very interesting account of the processes of decomposition in the metabolism of plants and animals.

After completing the study of the products of decomposition, Dr. Cohnheim gives a suggestive summary of the views held with regard to the mode of union of the elements present in the proteid molecule. It is noteworthy that in no part of the book is an account given of the various attempts to synthesise proteids.

At the outset of the following chapter, on the classification of proteids, the author shows a certain hesitation in adopting the usual method of classification, but ultimately decides that at present it is impossible to give a satisfactory classification based upon differences of chemical structure. He therefore practically adopts Hammarsten's latest classification, which, with some modifications, is essentially the same as that proposed by Hoppe-Seyler and Drechsel about fifteen years ago.

Limits of space will not permit one to give more than a brief reference to the remainder of the book. In the order of treatment of the subject, Dr. Cohnheim has adopted a significant departure from the order of classification.

An analogy is frequently drawn between the proteids and the carbohydrates in the sense that the native proteids are considered to bear to the primary products of their hydrolytic decomposition, namely, the proteoses and peptones, a relation similar to that which the more complex polysaccharides bear to the dextrins.

Under the influence of this analogy, Dr. Cohnheim deals with the chemistry of the proteoses and peptones before commencing his detailed account of the individual forms of proteid. One almost regrets that the author had not departed still farther from the usual order of treatment. Following Kossel's suggestion, he might first of all have dealt with the hexone bases and their anhydrides, the protones and protamines. Kossel originally proposed the name hexone-bases to mark the analogy

between them and the hexoses. The protones would, according to this scheme, be considered as comparable with the dextrins, and the protamines as comparable with starch. It is true that our knowledge is still too incomplete to enable us to carry the process still further, so as to trace with accuracy the connection between the protamines, on the one hand, and the proteoses and peptones on the other; but that need not prevent us from considering the subject in the order above described, especially since this arrangement has also the advantage of passing from the simple to the more complex. A short reference has already been made to the hexone bases, the protones and the protamines. To that account the following facts may be added. The protamines resemble other proteids in being lævorotatory, and have a toxic action similar to that of the albumoses. It is worthy of mention that, although the salts of the protamines with mineral acids are lævorotatory, those of the hexone base, histidin, are dextrorotatory. The protamines also resemble the proteoses and peptones in not being coagulated by heat.

Intermediate between the protamines and the native proteids lies a somewhat ill-defined class of proteids termed the histones. These have a well-marked basic character, being precipitated from their solutions by the addition of ammonia. They are not precipitated by heat unless a neutral salt of the alkalies be present, and even under those conditions they are incompletely precipitated. Within the organism they are never found in the free form; but always in combination with some other organic group, usually either nucleic acid or a pigment. It is asserted that they are occasionally found in the urine.

Their chemical properties place them in a class intermediate between the protamines and the simple native proteids. On account of their tendency to form compounds with other proteids, they appear to be well fitted to serve as precursors of the more complex forms of proteid. In neutral solutions they give precipitates with egg-albumin, serum-globulin, and caseinogen containing the two components in a fixed quantitative relation.

The most important recent advances in our knowledge of the proteoses are due to the work of Hofmeister and his pupils. They have applied the method of fractional precipitation by means of ammonium sulphate and of zinc sulphate to the separation of the proteoses resulting from the peptic digestion of various proteids, and, although it has not yet been found possible to separate by these means chemically distinct bodies, the complete separation of the proteoses into chemical individuals may be looked upon as a probable attainment in the near future. The chief difficulty of the separation is due to the fact that the proteoses, being all either of an acid or basic character, tend to unite together so as to form salt-like compounds. Only the briefest summary of the more recent results can be given here.

The proteoses may be divided into three classes.

The first class yields, on farther hydrolytic decomposition, a large quantity of monamido- and diamido-acids of the fatty series. It also contains a benzene radicle in which none of the hydrogen atoms are substituted for hydroxyl and a relatively large proportion of both loosely and firmly combined sulphur. It corresponds in type to Kühne's anti-group and, from the large proportion of diamido-acids which it yields, may be regarded as more closely allied to protamine than either of the two other classes. It is very resistant to hydrolytic agents.

The second class contains loosely and firmly combined sulphur, a benzene radicle in which one hydrogen atom has been substituted for hydroxyl and yields a relatively small quantity of monamido- and diamido-acids of the fatty series. It easily undergoes hydrolytic decomposition, and is termed the hemi-group.

The third class has been less thoroughly investigated. It is distinguished from the two former classes by the presence of a carbohydrate radicle, and is apparently absent from the molecule of many native proteids. One may regard the molecules of the majority of native proteids as being built up by the union of these three groups in varying proportions.

The chemical nature of the peptones is still the subject of much controversy. They are characterised mainly by not being precipitated by saturation of their acid solutions with ammonium sulphate, by giving a well-marked biuret reaction, and by yielding on farther hydrolytic decomposition the hexone bases amongst other products.

A detailed account of the individual native proteids is next given. Then there follows a description of the compound proteids which consist of one or more molecules of a simple proteid united with some other body, which may be either nucleic acid, chondroitinsulphuric acid, a pigment, or a nitrogenous derivative of the polysaccharides probably bearing the same relation to mucosamine or glucosamine as starch does to glucose. Cohnheim places the nucleoalbumins amongst the simple proteids, and suggests phosphoglobins as a more suitable name for the group.

The book terminates with a description of the chemical and physical properties of the albuminoids.

In conclusion, one cannot but feel that Dr. Cohnheim has earned the gratitude of both chemists and physiologists by his thorough review of the present state of knowledge of the chemistry of the proteids. In no other branch of chemistry is the literature scattered throughout so many journals of very diverse branches of science, and this makes the task of reviewing the literature a most arduous one.

As a work of reference the book is indispensable to all workers in physiological chemistry. J. A. Milroy.

MODERN LENS MAKING.

Contributions to Photographic Optics. By Dr. Otto Lummer. Translated and augmented by Prof. Silvanus P. Thompson, F.R.S. Pp. xi + 135. (London: Macmillan and Co., Ltd., 1900.)

Dr. Lummer and Prof. Thompson have given us in the above volume a thoroughly practical treatise on that part of optics with which it deals, and the book does much to prove the truth of a statement of the translator's preface: "In fact the science of the best optical instrument-makers is far ahead of the science of the text-books."

The history of the book is interesting. Dr. Lummer, when working up the subject of photographic optics for a new edition of Müller-Pouillet's text-book of physics

"looked about fruitlessly for a guide"; he found nothing to help him, and the volume now under review, which has been translated and amplified by Prof. Thompson, is the result.

Let us consider the problem; the photographer needs to produce on a flat surface an exact picture of a distant object. To take in a wide field of view the plate must subtend a considerable angle at the centre of the lens; the rays of light traverse the lens in very various directions, some are parallel to its axis, others are oblique, and the angle between them and the axis may reach 30° to 40°.

It is impossible to attain this result with any single lens; we must examine, then, in what respects an actual lens differs from the perfect instrument of Gauss's theory, what are its defects, and how they are to be remedied.

Now this theory is an approximation for real lenses depending on the assumption that the angle between any ray and the axis of the system is so small that all its powers above the first may be neglected.

We wish to inquire, then, what are the conditions which must hold in order that a refracting system may produce an image coinciding with that given by Gauss's theory, even when we retain in our mathematical theory powers of the obliquity above the first. This was done by L. von Seidel in the years 1856, 1857 (*Astronomische Nachrichten*, 835, 871, 1027-1029) for the case in which powers of the obliquity up to the third are retained. His work is hardly known in England. He found that to this degree of accuracy a perfect image could be obtained provided five separate equations of condition between the curvatures and refractive indices of the lenses and their distances apart were satisfied. These five conditions, which we may denote by $S_1 = 0 \ldots S_5 = 0$, are sufficient for all cases in which the light employed is of definite refrangibility; to correct, however, for dispersion, two other conditions are required, and the modern photographic objective, possible only in consequence of the discovery by the Jena factory of special "anomalous" glasses, is the outcome of the attempt to satisfy these conditions.

In the work before us no attempt is made to prove the above equations; this is not part of the scheme of the book, but it is shown that to each condition a distinctive physical meaning can be attached, and this physical meaning is brought into very clear light.

The first equation, $S_1=0$, is the condition that the image of a point on the axis may be a point, free, therefore, from aberration, even when the full aperture of the lens is used.

Let this be satisfied, and suppose the point source to move away at right angles to the axis to some neighbouring position, let the refracted beam be received on a screen perpendicular to the axis; in general, a blurr of light, more or less pear-shaped, will be formed at the screen; in some positions the narrow end of the pear is towards the axis, in others it is removed from it. The shape varies as the screen is moved, but unless the lens is corrected a point image is never formed. This is the defect or aberration called coma, so beautifully shown by Prof. Thompson to the Physical Society last session.

Now we know that when a *small* pencil of rays is obliquely refracted, the refracted rays diverge from two focal lines which lie in perpendicular planes; and we may look upon the finite pencil as composed of a series of small pencils incident at different parts of the lens. To each of these corresponds two focal lines, a primary and a secondary. But the refraction produced by the lens is such that the primary line belonging to a small pencil traversing the lens near its edge does not coincide with that of the central pencil. The primary focal line has a different position for each of the small pencils into which the finite incident pencil has been resolved; if, for a moment, we look upon the primary line as an image of the source, the position of this image depends on the portion of the lens by which it is formed. The next step, then, is to superpose these partial focal lines so as to form two single, primary and secondary, focal lines for the whole pencil, and this is the meaning of Seidel's second condition, $S_2=0$. This condition, which was known to Frauenhofer, is shown to be identical with a law distinguished as the Sine-law, which states that if P be a point on the axis of the system, and Q its image, and if a, a' be the angles which an incident ray through P and the corresponding refracted ray through Q make with the axis, then $\sin a/\sin a'$ is a constant for all rays. If a small object be placed at P, perpendicular to the axis, and a perfect image of this be formed at Q, then, as von Helmholtz showed, the ratio $\sin a/\sin a'$ measures the linear magnification of the image. The connection between this and the physical meaning of the condition $S_2=0$ is an obvious one.

But if this condition be satisfied, we are far from having a point image of our source; we have, instead, two linear images—one lying at right-angles to the axial plane through the point, the other, the secondary image, lying in that plane. If, instead of considering the image of a point, we deal with a plane cutting the axis at right-angles in P, we get, as the image of this plane, two curved surfaces, the one made up of primary lines, the other of secondary lines; these both cut the axis at right-angles in Q, the image of P. If by any means we can make the primary and secondary lines coincide, we shall have a point image of our point source; and this is done if the condition S_3 is satisfied. Such an image is said to be stigmatic, or sometimes an-astigmatic. If this be done for the whole field, the curved surfaces move up to coincidence; the image of the plane is a single surface, not two; in general, however, this image surface will be curved, and as we cannot dish out our photographic plate to get it, we must, if possible, make it plane. The equation $S_4=0$ expresses the condition for this.

Thus, if these four conditions are satisfied, we obtain a plane stigmatic image of any object lying in a plane normal to the axis of the lens.

But this alone is not sufficient to give us a perfect image; it must be similar to the object, there must be no distortion. It is found that the equation $S_5=0$ expresses the condition for this.

In some such manner as the above, Dr. Lummer and Prof. Thompson explain the meaning of the five conditions of no aberration, and then proceed to show how each is satisfied.

For the details of this the reader must refer to the book; there is one other point, however, which it is desirable to follow up more completely here. The

system must be free from chromatic aberration. Now let us, for simplicity, deal with two lenses in contact; let f, f' be their focal lengths, μ, μ' their refractive indices, and let $1/\nu$ $1/\nu'$ represent their dispersive powers, so that $\nu=(\mu-1)/(\mu_v-\mu_r)$, μ_v and μ_r being the indices for the rays it is desired to achromatise, while μ refers to some mean ray.

Then the condition for achromatism is

$$\frac{1}{\nu f}+\frac{1}{\nu' f'}=0.$$

Now it is shown in the book that for this case the condition that the field may be flat—Seidel's fourth condition—reduces to

$$\frac{1}{\mu f}+\frac{1}{\mu' f'}=0.$$

Thus the focal lengths must be of opposite sign, and the lens with least focal length—the concave lens that is in a photographic combination—must have the greatest refractive index. But, in order to satisfy the condition for achromatism, this same lens must have the greatest value for ν'.

Now achromatic lenses have usually been made by combining a convex lens of crown glass with a concave lens of flint; with such glasses, however, it is found that when μ is large ν is small, and *vice versâ*. Thus, for example, ordinary light flint has a greater refractive index than silicate crown glass, and hence an achromatic combination is possible; but since the value of ν for such flint is less than for crown, the combination when made will not give a flat field.

Dr. Lummer defines as an "old achromat" a pair of achromatised lenses made of such glass.

One of the results, however, of the experiments of Abbe and Schott at Jena has been the discovery that by the addition of barium salts a crown glass can be obtained having both a high refractive index and a high value for ν. Such a glass could take the place of the flint glass in an achromatic combination, and with this advantage, that the condition for flattening the field could be nearly, if not completely, satisfied.

The condition above given for a flat field was discovered by Petzval in 1843; in principle it had already been published by Airey ("Coddington's Optics," 1829). Von Seidel, however, was the first to point out that it was impossible with the lenses then available to satisfy both it and the condition for achromatism, and it was not until the Jena glass became available that an achromatic lens with a flat field was possible. Such lenses are called by Lummer "new achromats."

Having shown, in the first eight or nine chapters of the book, what are the conditions to be satisfied, Prof. Lummer proceeds to describe the various ways in which this is done in practice. The condition of no distortion is readily satisfied by combining two identical sets of lenses symmetrically placed into a double object glass with the stop midway between. These, if of the new "anomalous" glasses, can have a flat field. But such a combination will not be completely stigmatic; to secure this, other conditions must be satisfied besides those which are possible in a symmetrical combination, and the best result has been obtained by combining, in what is known as an anastigmatic-aplanat, a new achromat with an old achromat. The astigmatic effect of the old achromat is opposite to that of the new; hence by the combination it is possible to secure a flat image which is also stigmatic and achromatic, while, by adjusting the distance between the lenses and properly placing the stop, the condition of no distortion is satisfied.

Details of combinations satisfying these various conditions are given in the book, and not the least of Dr. Thompson's services are the chapters in which he calls attention to the excellent work done by various well-known English makers. His description of Dallmeyer's Tele-objective is specially welcome, while Miethe's two views of Munich from a distance of about two miles—the one taken with an ordinary lens, the other with his tele-objective—show what a powerful weapon the latter is.

The appendix contains some more detailed accounts of von Seidel's analysis, and also a valuable example of the computation of a lens.

The book is published by Messrs. Macmillan and Co. in their usual admirable style, and supplies a very real addition to the literature of a subject too much neglected in England. R. T. G.

OUR BOOK SHELF.

A Handy Book of Horticulture. By F. C. Hayes, M.A. Pp. xi + 225. (London: John Murray, 1900.)

THIS is a little book intended "for the class of fairly intelligent young men who are placed in sole charge of small gardens, who have little natural aptitude for gardening and no training, and who look in vain to their employers for teaching or suggestions of any kind." The questions naturally arise how such men come to have charge of gardens, and whether any book is likely to be of material service to them. For a class of better informed readers with a real interest in the subject the present book is better adapted, as the directions are simple and clear. The practical instruction conveyed is good, but, although the book is not intended for botanists, we may fairly look for accuracy and correct spelling of names.

In the following passages we have examples of loose writing, which are not the only ones that might be found:—

"The lilium is a popular family of hardy, bulbous flowers. No garden should be without a variety of them, but the species is so numerous that it would be impossible in one brief chapter to lay down general rules for their culture."

Here is another paragraph which is not remarkable for accuracy:—

"Speaking generally, a fern may be defined as a plant which bears leaves only and no flowers. The name of their order is Cryptogamia, *i.e.* hidden flowers; they have organs which produce spores, but the attractive petals are absent, and the spore cases are hidden away or take strange forms."

On the following page we have such misspelling as Calcidonicum and tigranum; elsewhere we find nemerosa, pyracanthus, azalias, Charles Lefebre; while the use or disuse of capital letters seems to be entirely a matter of caprice.

The Construction of Large Induction Coils; a Workshop Handbook. By A. T. Hare, M.A. Pp. 155. 35 illustrations. (London: Methuen and Co., 1900.)

THIS book, written by an amateur primarily for amateurs, will be found of the greatest use for all those, amateurs and professionals alike, who desire to construct Rhumkorf induction coils according to the most approved methods.

It is, indeed, so far as the present writer is aware, the only modern work which deals with the construction of large coils from a thoroughly practical standpoint. It describes in every detail the making of the apparatus, and contains much valuable information as to the general design of coils, the methods of winding and the processes of insulation, which hitherto have been the carefully preserved secrets of the very few makers of coils of the more powerful descriptions. Questions of cost are not omitted, while special chapters are devoted to contact breakers of the mercury, hand and electrolytic types.

The discovery of the Röntgen rays, and the important application that these have found in surgical and medical practice, together with the increasing employment of high tension electrical discharges in wireless telegraphy, spectroscopic analysis and other fields, have brought about a great demand for Rhumkorf coils of large size. The need for a book such as the one under review has therefore become increasingly felt of late years, and the only matter for regret is that the author did not give to the public the results of his experience at an earlier date.

The book is clearly written, well printed and well illustrated. A. A. C. S.

The Structure and Life-History of the Harlequin Fly (*Chironomus*). By L. C. Miall, F.R.S., and A. R. Hammond, F.L.S. Pp. viii + 196; plate and text illustrations. (Oxford: Clarendon Press, 1900.)

THE perfect insects of *Chironomus* are conspicuous objects on our windows, or may be seen dancing in swarms in the open air, and are often called "gnats," to which they have considerable resemblance; and, like gnats, the antennæ of the males are very plumose. The larvæ are found at the bottom of standing or slowly-running water, and those of some species are known, from their colour, as "blood-worms," while those of other species are green. The insects are easily collected and reared, and present many points of interest; and the work before us gives a very clear and fairly elaborate account of the structure and habits of these insects in their various stages. The life-histories of insects present an inexhaustible field for the investigations of any observers who care to devote their attention to this branch of entomology; and books like the present will give the beginner a very good idea of the best way to work on similar lines. Hitherto the Diptera, though one of the largest orders of insects, have been strangely neglected in England, and we have not even a good descriptive book on the order, though almost every Continental country has a good monograph in its own language. The interest felt in mosquitoes, however, at the present time will probably spread to other insects of the same order; and thus we are likely to see the study of their life-histories leading to that of the Diptera as a whole, instead of interest in the order generally, leading to researches into its life-histories, as has been the case with some of the other orders of insects.

The bulk of this work is too technical and too elaborate to admit of its being discussed in detail, and it contains much useful general information relating to allied species, nor are the parasites of the larvæ left unnoticed. One remark strikes us as specially interesting: "No insect is known to us which has more completely departed from the habits and structure of an air-breathing animal. Yet even here we find visible proof of descent from a terrestrial insect with branching air-tubes."

In an appendix we find a section on "Methods of Anatomical and Histological Investigation," and an additional note by Mr. T. H. Taylor on the swarming and buzzing of Harlequin flies. The book concludes with a good bibliography and index. W. F. K.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the Nature of the Solar Corona, with some Suggestions for Work at the next Total Eclipse.

IN an article on the corona, published in the November number of the *Astrophysical Journal*, I suggested a method by which the existence of the Fraünhofer lines in the spectrum of the corona might be detected. The method was based on the supposition that the light emitted by the particles, in virtue of their incandescence, so overpowers the reflected sun-light that the lines are invisible. That the coronal light is strongly polarised is well known, and there is scarcely any doubt but that the polarised light is reflected sun-light. If, now, a Nicol prism be placed before the slit of the spectroscope in such a position as to transmit the polarised radiations, these will be allowed to pass with almost undiminished intensity, while the emitted or unpolarised light will be reduced in intensity by one-half. The great change in the ratio resulting might easily be sufficient to bring out the dark lines distinctly. I feel firmly convinced that this experiment should be tried at the Sumatra eclipse of next May, for I have successfully accomplished it in the laboratory with an artificial corona. It was found that a gas flame in a strong beam of sun-light shone with a pure bluish-white light, due to the reflection or rather scattering of the sun-light by the minute carbon particles.[1] The flame thus illuminated showed the Fraünhofer lines distinctly, but by reducing the intensity of the sun-light a point was reached at which they disappeared, and the spectrum appeared continuous. The light scattered by the flame was found to be completely plane polarised in certain directions, giving us just the required conditions, namely, particles emitting a continuous spectrum, and scattering a polarised solar spectrum. In front of the slit of the spectroscope a Nicol prism was arranged in such a manner that it could be drawn into and out of position by a cord. The Fraünhofer lines could be made to appear by sliding the Nicol in front of the slit, and disappear by drawing it away. While it does not by any means follow that the use of a Nicol on the actual corona will bring out the lines, the experiment seems to be well worth trying, as it would furnish further information regarding the relative intensity of the emitted and reflected light.

Another interesting point is that the minute particles in the flame do not scatter the longer waves, the flame reflecting practically no red or orange light. Thus the Fraünhofer lines can only be traced to about the D lines. By reducing the intensity of the sun-light they disappear, first in the yellow, then in the green, blue and violet in succession. This indicates that our chances of detecting the lines in the spectrum of the corona will be greatest in the photographic part of the spectrum. Moreover, it appears to explain the absence of radiant heat in the light sent to us from the corona, the particles being too small to scatter these longer waves to any appreciable extent. Abbott, of the Smithsonian party at Wadesboro', found the corona cold in comparison with his bolometer, and infers from this that the corona neither reflects sun-light nor emits light in virtue of incandescence, expressing the opinion that the luminosity is analogous to that of vacuum tubes transmitting electric discharges. It seems to me that the polarisation of the coronal light makes this theory untenable, and that the absence of heat rays can be explained fully by the small size of the particles. I am aware that the absence of radiant heat in the *emitted* light has yet to be accounted for. My own notion, based on experiments which are now in progress, is that the reflected or scattered light is vastly in excess of the emitted, and that the absence of the Fraünhofer lines is more probably due to the line-of-sight motion of the particles than to simple drowning out by emitted light.

My experiments on the ratio of emitted to scattered light of a body brought to incandescence by powerful solar radiation are not yet completed, consequently I do not yet feel prepared to make any very positive statement in regard to this matter. A

[1] Since writing the above I have found that the reflection of light by a flame has been described by Mr. Burch and Sir George Stokes indepen dently. It was noticed also by Soret at a still earlier date (1875) as I have subsequently found.

full account of this work will appear shortly in the *Astrophysical Journal.*

Any observers planning to use a Nicol prism in connection with a spectroscope in the manner described will find a gas or candle flame illuminated with a beam of sun-light, concentrated by means of a large mirror or lens, extremely useful in making preliminary experiments.

For work on the polarisation of the corona, I believe that the artificial corona, which will be described next week, will be found most useful for preparatory work. Not only is it polarised, and polarised in the same way as the real corona, but it resembles it in every respect, and can be easily made of the same brilliancy. It would be well to work with particles of different size, giving different percentages of polarisation, and the picturesque refinements for producing the polar streamers could, of course, be omitted. A lamp with a ground glass globe might be used to advantage, giving a distribution of polarisation more nearly like that of the actual corona.

Data regarding the plane of polarisation in the streamers would be useful in formulating a theory of the streamers. These, it seems to me, can be conceived as formed in two ways: they may be streams of coronal particles moving in curved paths, in which case the plane of polarisation should be everywhere strictly radial, or, what is extremely improbable, they may be caused by divergent beams of light coming from the polar regions of the sun and moving in curved paths owing to the rapid decrease in the refractive index of the sun's atmosphere in an outward direction. If this were the case, the plane of polarisation would turn with the streamer. This latter hypothesis is extremely visionary, and I do not present it seriously, for it is almost impossible to conceive of any way in which the isolated beams of light could be formed, unless, perhaps, by vortex funnels more highly luminous than the surrounding surface of the sun. Such fanciful speculations are hardly worth indulging in, though they have interested me for the moment in connection with the matter of possible curvature of light rays in the sun's atmosphere, alluded to in a recent paper by Julius in the *Astrophysical Journal.* R. W. WOOD.

University of Wisconsin.

The Alleged Decadence of German Chemistry.

As a man of business, more or less interested in the course of chemical discovery in so far as it affects chemical products of market value, I have for so many years been accustomed to take note of the rapid strides made by Germany in the chemical industries, that the statement contained in the article by "W. J. P." in your issue of December 27 (p. 214) has struck me with amazement. The writer says that "all students of contemporary chemical literature will agree that in Germany the science of chemistry has been in rapid decadence during recent years." This statement seems to me so completely at variance with my own experience that I have consulted chemical friends as to its accuracy, and I cannot find any chemist who agrees with this verdict. The consensus of opinion is, in fact, all in the opposite direction. "W. J. P." himself admits, as a generally recognised principle, that supremacy in any particular industry goes hand in hand with supremacy in the related sciences. Every one of the discoveries recorded in his own paper has been made in Germany, and he himself points out that the new industry is "almost wholly of German origin." Of course, as an English merchant, I hold no brief for German products, but having long ago recognised the importance of the connection between science and industry, which the author emphasises, and seeing what Germany has been doing of late years, I perhaps innocently attributed the progress of that country to their superior system of training in chemistry and related sciences, and to the readiness of their manufacturers to avail themselves of the results of scientific discovery. For the sake of British industry, I shall be only too glad to learn that I was mistaken; but since no chemist of my acquaintance agrees with the writer, and since he himself puts forward a whole body of German discoveries in order to tell us that chemical science is undergoing "rapid decadence" in that country, I cannot but feel that there is such a glaring contradiction between the facts recorded and the conclusions arrived at by the writer that some further explanation as to his meaning is necessary.

S. N. C.

Secondary Sexual Characters.

MR. POCOCK (p. 157) has replied to my letter, but he has not replied to my reasoning. It is no reply to say that it may be doubted whether my hypothesis is an improvement on certain others, when no reasons are given for the doubt. It is no argument to say that a problem is insufficiently supported by evidence, and may be true or false. A problem may be solved, but it cannot be either true or false, nor can it be supported by evidence. Mr. Pocock himself in his article attributed the colour of the male nilghaie and other antelopes to "male katabolism," which he now says is nothing but an imposing substitute for the "vital force" of the pseudo-scientific realists. I quite agree with him, and only hope that in future he will not explain male peculiarities by attributing them to male katabolism.

It is very difficult to reason with a naturalist who uses the terms "struggle for existence" and "influence of external conditions" as equivalent to "selection." I quite understand that to the Darwinian the only important action of external conditions is the selective action, the survival of the fittest. But the Darwinian does not appear to understand his opponents' conception of the modifying non-selective action of external conditions. Mr. Pocock does not distinguish between variations and modification. If any cause acts on *all* the males of a species and makes their colours dark or black, what effect can selection produce? If the dark colour is harmful, the species will become reduced or extinct. But selection cannot, as Mr. Pocock suggests, "check" a general modification due to a general cause without eliminating the species.

Thus the question which Mr. Pocock raised in his original article, and which he now "sets aside," the question of the initial cause of sexual modifications, is the essential question of the whole subject, and cannot be set aside in any rational discussion of the facts. Even supposing that the variations are different and not general, and that those which are beneficial are selected and preserved, selection offers no explanation of the fact that in so many cases the peculiarities in question are inherited only by the male sex. Mr. Pocock, in discussing the uses of coloration and markings, was obliged to refer to cases in which the males differed from the females both in colour and in horns. He has not yet realised the truth that no theories based on the conception of selection afford any explanation of unisexual inheritance.

Penzance, December 17, 1900. J. T. CUNNINGHAM.

The Word Physiography.

WITH reference to the question of the early use of the word Physiography to express the comprehensive study of Nature, to which you refer on p. 207 of your last issue, I should like to call attention to a fact which appears to have been almost forgotten.

The title-page of a "Dictionnaire des Termes usités dans les Sciences naturelles," published in Paris in 1834, bears as a motto the words—

"Profectò physiographiam qui colit, ullo pacto metam perfectioris cognitionis feliciùs non attinget, quàm si aliquot dies terminis perdiscendis tribuerit."—*Linné.*

I have tried, but without success, to find this quotation in the works of Linnæus; perhaps some of your readers may be able to supply the reference. The word Physiography was certainly current in Sweden about the middle of the eighteeenth century, as in the obituary notice of Torbern Bergman, read at the Stockholm Academy of Sciences in 1786 (which I know only in the German translation), it is mentioned that he became a member "der Physiographischen Gesellschaft in Lund, 1776." "Minerva" for 1900—1901, however, states that the Physiographical Society of Lund, which still exists, was founded in 1778 for the study of the scientific and economic conditions of the province of Scania. There was at the same time a Cosmographic Society in Upsala, and the two names seem to have been used much in the same sense.

I think it possible that the word Physiography was introduced in Sweden by Linnæus as a substitute for Cosmography, the ancestor alike of the Physiography of South Kensington, and the Physical Geography of the older text-books.

HUGH ROBERT MILL.

Artificial Rain.

AFTER the magisterial words of Prof. Cleveland Abbe, as reported in your issue of December 13, 1900, it requires some courage to offer a possible instance of "artificial" rain. I was near Bolton Abbey railway station on November 26 last. The atmosphere was perfectly calm, and a thin white mist enveloped the landscape. A number of land-blasting explosions took place in some limestone quarries, perhaps a quarter of a mile away. At a very short interval after these there occurred a very little shower or sprinkling of rain, just sufficient to cause me to put up my umbrella in preparation for more. The extreme brevity of the shower, and the peculiar conditions under which it occurred, arrested my attention, and led me at once to refer it to the explosions which had just taken place.

Keighley, December 22, 1900. C. H. B. WOODD.

IN an article on artificial rain in your issue of December 13, 1900, Prof. Abbe alludes to "the popular belief that rain follows great battles," which is now often—incorrectly, as the article points out—explained by and used as an indication of some effect produced on the clouds by the explosion of the gun-powder.

It is interesting in this connection to observe that the belief about rain following battles was held many centuries before the invention of gunpowder. Plutarch, in his life of Caius Marius, writes:—"It is observed, indeed, that extraordinary rains generally fall after great battles: whether it be that some deity chooses to wash and purify the earth with water from above; or that the blood and corruption, by the moist and heavy vapours they emit, thicken the air, which is generally liable to be affected and altered by the smallest cause." (Langhorne's translation). The inference is that the belief was the result of a preconceived idea, and that the gunpowder explanation was therefore wasted on a theory which was not grounded on observation at all. M. T. TATHAM.

Northcourt, Abingdon.

PROGRESS IN METALLOGRAPHY.

THE application of micrographic analysis to the study of alloys has given to the metallurgist a new and important field of investigation, and every improvement in the established methods is worthy of attention. Some of the latest suggestions are made by M. Henri le Chatelier in the *Bulletin de la Société d'Encouragement* for September last, the most noteworthy being in connection with the final stages of polishing. It is necessary for this work that the polishing powders should be perfectly classified according to the dimensions of the particles. The method of sorting by means of levigation, described by M. Osmond, is defective, owing to the fact that the salts of lime in ordinary water cause coagulation and rapid deposition of minute particles suspended in water. Caustic lime and acids induce even more rapid settling, a fact that has proved of great commercial importance in the treatment of ore slimes by cyanide in South Africa.

To overcome this difficulty the powders are heated with nitric acid, washed thoroughly, and allowed to settle in distilled water containing 0·2 per cent. of ammonia. When treating ten grams of powder in a litre flask, nine-tenths of the liquid are siphoned off at the following intervals of time: a quarter of an hour, one hour, four hours, twenty-four hours, and eight days. The third deposit is useful in polishing hard metals such as iron, but the fifth and last deposit affords the best polishing powder. Minute care is taken to avoid any admixture of dust or dirt with these powders, which can now be bought in Paris mixed into a paste with soap, and contained in tin tubes such as are used for oil colours.

A number of materials for the manufacture of these powders have been tried. M. Le Chatelier finds that alumina prepared by calcining ammonium alum is the best, as far as speed of polishing is concerned; but oxide of chromium, obtained from the combustion of bichromate of ammonium, answers fairly well in the treatment of iron and steel, and is better than alumina for soft metals such as copper. Oxide of iron is far less advantageous than these substances, its action being very slow. The soap

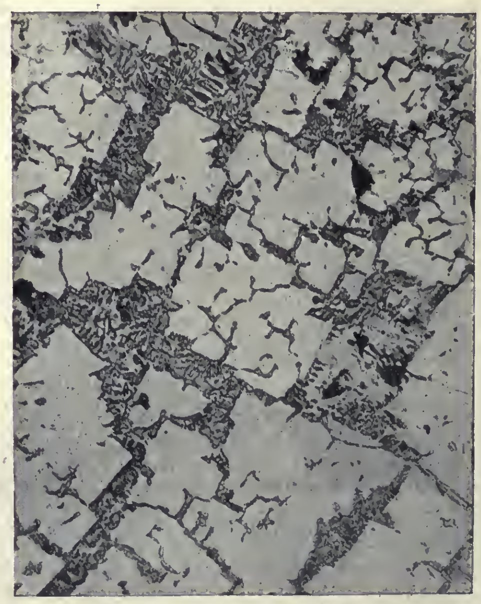

FIG. 1.—Crystals of Al_2Cu.

preparations are applied in the ordinary way to discs of wood or metal covered with skin or cloth and capable of being revolved at high velocity, the whole operation of polishing proper being carried through by their aid in five minutes.

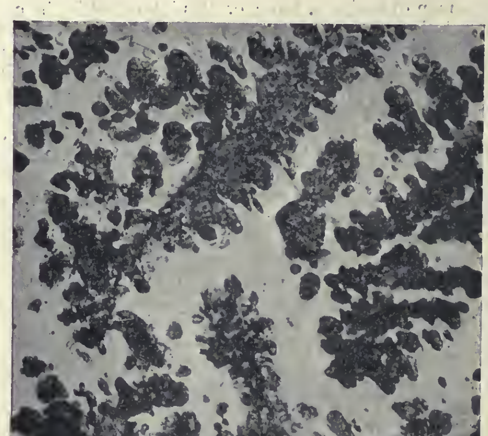

FIG. 2.—Compound near AlCu.

For examining and photographing the polished and etched specimens under the microscope, M. Le Chatelier proposes the use of monochromatic light such as that derived from an electric arc in mercury vapour, with

suitable screens between the source of light and the object to be illuminated; but it appears doubtful whether enough light can be easily obtained in this way for very high magnifications.

With regard to the selection of the specimens to be examined, it is well known that much time is wasted when working out a complete series of alloys of two metals. It is necessary to prepare, polish and etch a series of specimens, many of which will present no features of interest when examined under the microscope. M. Le Chatelier proposes to shorten the search for typical alloys by melting together two superimposed layers, each consisting of a pure metal, the lighter one being on the top. If no alloys are formed of greater density than the heavier metal, and the crucible is allowed to cool undisturbed, a culot can be obtained which, on being sawn through vertically, shows a complete gradation from one pure metal to the other, passing through the whole series of alloys, which can then be studied in one specimen. In this way he prepared a number of series, the three illustrations (Figs. 1, 2 and 3) being from

FIG. 3.—Crystals of $AlCu_3$.

photographs of different parts of a single specimen showing the aluminium-copper series. Fig. 1 shows crystals of Al_2Cu; Fig. 2, crystals of a compound of undetermined composition which is not far from that expressed by the formula AlCu; Fig. 3 shows crystals of the compound $AlCu_3$. It would seem that the exact percentage of any particular part of a specimen prepared in this way must be a matter of uncertainty, but there is no doubt that, in the hands of M. Le Chatelier, the method has already yielded some interesting results.

T. K. ROSE.

SOME RECENT ADVANCES IN GENERAL GEOLOGY.

AMONG the recent researches on organic remains none are of greater geological interest and importance than those relating to the Radiolaria. The tiny siliceous structures which belong to this Order of Protozoa have long been recognised in our formations, but the part they have played in building up portions of the stony structure of the earth has not until lately been realised. The most striking evidence was that brought forward by Prof. Edgeworth David and Mr. E. F. Pittman (*Quart. Journ. Geol. Soc.*, vol. lv. p. 16, 1899). They describe a great series of siliceous limestones, jaspers and claystones, with interstratified coral limestones and plant-beds, and submarine tuffs, the whole attaining a thickness of over 9000 feet, and extending over many hundred square miles in New South Wales. In the bulk of these rocks Radiolaria are present at the rate of about one million to the cubic inch, and among the forms Dr. G. J. Hinde has recognised twenty-nine genera and fifty-three species. Taken as a whole, the deposits are fine-grained, and bear evidence of having been laid down in clear sea-water, beyond reach of any but the finest sediment. They do not indicate any very considerable depth of water; but they tell of a vast lapse of time, and of conditions which prevented the dispersal over the area of coarse detritus. What exactly were these conditions it remains for future research to discover. In this country, in Devonshire and Cornwall, the occurrence of radiolarian cherts, both of Ordovician and Carboniferous ages, has been made known through the observations of Dr. Hinde, Mr. Howard Fox and Mr. Teall. The more prominent of these rocks are found in the Lower Carboniferous formation of Coddon Hill near Barnstaple, where the chert-beds have long been known, although their organic origin was not until recently discovered. The freedom of the beds from mechanically-formed detritus has led to the supposition that these strata were deposited in deep water and at some distance from the coast, although the associated strata above and below the chert-beds do not lend support to the hypothesis. The fact is that at the present time the only extensive radiolarian deposits known to be in process of accumulation are in the deeper oceanic regions.

Radiolaria, while entirely marine, are widely distributed, and they can exist at various depths in deep and shallow seas. It may be surmised, therefore, that in shallower areas coral-reefs may have acted as barriers to the dispersal of terrestrial *débris*. Hence in our explanations of the physical conditions of the past we must be guided by the general characters of the sedimentary strata in which bands and beds of radiolarian chert occur, rather than by the evidence of the chert itself. There is, however, little doubt, from the wide distribution of these lowly forms of life, that they may prove of considerable importance in the identification of horizons, although, as might be expected from their present geographical and bathymetrical ranges, some specific types have been of long geological duration.

In the coast ranges in California, and again in Borneo, such radiolarian rocks of Jurassic, or possibly Lower Cretaceous age occur, and it is noteworthy that Dr. Rüst has remarked that "the differences in the Radiolaria from these two rock-divisions are not very striking." (See Hinde's "Description of Fossil Radiolaria from Central Borneo," 1899.)

The question whether the Wealden strata which are essentially freshwater should be grouped as Jurassic rather than Cretaceous has been raised by geologists in the New as well as in the Old World, who have argued that the Wealden plants, fishes and reptiles are Jurassic rather than Cretaceous in character. There has never been any question in this country that the Purbeck and Wealden Beds are intimately connected both stratigraphically and palæontologically, and it has been held by some geologists that locally the Wealden Beds and Lower Greensand bear also evidence of continuous deposition. The subject was lately discussed by Mr. G. W. Lamplugh (Brit. Assoc., Bradford, 1900), who points out that in Dorset, Hampshire and Surrey there is evidence of the close stratigraphical connection between Wealden and Lower Greensand, that part of the

freshwater Wealden must represent true marine Lower Cretaceous beds elsewhere, and that consequently it is equally erroneous to classify the Wealden series entirely with the Jurassic system or entirely with the Cretaceous.

If the planes of division between our formations are more often than not ill-defined, so also are those between the main systems. Between our Palæozoic and Mesozoic strata there has never been a very well-marked boundary, for some authorities have placed the Permian with the older division and some with the newer.

The tendency of recent investigations in the midland areas is to show that a considerable series of red beds which have been regarded as Permian are truly portions of the Coal-measures, while it is evident that the Magnesian Limestone series is stratigraphically united more closely with the Triassic strata. In Britain the main mass of the Permian (Magnesian Limestone series, &c.) lies unquestionably with great discordance on various subdivisions of the denuded Carboniferous and Devonian rocks. Abroad in many areas, in India, Australia and elsewhere, there appear connecting links in strata grouped as Permo-Carboniferous; but it is a question whether the original Permian is anything more than a provincial set of strata, unentitled to rank with a system (see C. R. Keyes, *Journ. Geol.*, Chicago, vol. vii. p. 337, 1899).

As the history of the successive strata in different countries becomes better understood, so it becomes possible more closely to parallel the life-epochs which are represented in the rocks. Such life-epochs do not of course correspond with the sedimentary changes which are recorded by the rocks themselves, and hence a double system of grouping becomes needful. In our own country this has been long apparent, and the successive groups of strata which are so well established in the Ordovician and Silurian systems of Wales, the Lake District and the Southern Uplands of Scotland require distinct stratigraphical terms, while the life-history and the correlation of the subdivisions are indicated by the zonal groupings based on zoological evidence. The representation on maps and in sections of the main stratigraphical groups, or geological formations, is essential in order to show the physical structure of a country, not only in reference to economic questions, but also in regard to the influence on the present scenery of the rocks and the movements to which they have been subjected. Different types of landscape and the evolution of river systems are engaging a good deal of attention, notably in the United States; and the study has led to the introduction of a large number of terms which are rather difficult to remember, but the more important are explained in Mr. J. E. Marr's "Scientific Study of Scenery."

Increasing attention is given to the great movements which have affected the rocks especially in mountain regions. The pioneering work of Heim in Alpine regions has been utilised and developed in the most brilliant manner by Lapworth and Rothpletz and many others. The old ideas of reversed faults have been, so to speak, magnified into great earth movements, whereby huge masses of country have been overfolded, fractured, and overthrust, the older being pushed over the newer. On a small scale such overthrusts were long ago recognised in some coal-fields by the name of overlap faults, and the displacement was measured by yards—now it is sometimes reckoned by miles. Moreover, not only in Highland regions where the secret inferred by Nicol was unravelled by Lapworth have these mighty overthrusts been made manifest, but on a comparatively small but by no means unimportant scale they have been traced out and pictured in the Cretaceous rocks of the Isle of Purbeck by Mr. A. Strahan. The same observer has drawn attention to other overthrusts in the great Coal-field of South Wales.

All sorts of complicated structures due to cross-folding and faulting, to successive horizontal displacements and twisting, have been produced in mountain regions; and Dr. Ogilvie Gordon has dealt exhaustively with the subject in a paper on the torsion-structure of the Dolomites (*Quart. Journ. Geol. Soc.*, vol. lv. p. 560). To quote one sentence from her paper will, perhaps, be enough to give an idea of the puzzles she has attempted to solve: "Anticlines have been twisted round synclines, and the rocks in the synclines have themselves been twisted and distorted, buckled up and depressed, overthrust and faulted normally, cross-faulted and cleaved, to an extent that has not hitherto been realised." We may add that the subject of torsion-structure has been examined mathematically by Mr. J. Buchanan (*Phil. Mag.*, vol. l. p. 261).

The evidence of great folds and flexures, accompanied by overthrust faults, has lately been brought more fully to light in the Malvern region by Prof. T. T. Groom, while in the Lake District the field labours of Mr. J. E. Marr and Mr. A. Harker, as recently expounded (*Proc. Geol. Assoc.*, vol. xvi. August 1900), indicate that the country has there been affected, not only by overthrust faulting, but by more or less horizontal displacement, termed "lag" faults, whereby lower and older strata have been moved more rapidly than newer overlying strata, which consequently have lagged behind. Other faults, called "tears," are described, where, during these movements, rents have occurred in the shifting masses of strata without occasioning much vertical displacement.

In very many cases along fault-planes there has been produced a kind of breccia due to the effects of displacement, but more striking results of such action have lately been made known in the production of conglomerates. In such cases the effects of earth-movements have not only fractured, but actually worn away, the edges of the shattered rocks. In the Isle of Man, where the Manx slates have undergone acute folding followed by intense shearing, the shear-cleavage has cut and displaced bands of grit and has actually rounded the fragments so as to produce what Mr. Lamplugh has termed a crush-conglomerate. His observations have borne good fruit elsewhere. Mr. C. A. Matley has described crush-breccias and crush-conglomerates in Anglesey, where they occur "along zones of powerful crushing, especially in areas where the soft, fine-grained, slaty rocks alternate with tougher and more brittle strata, such as grits and quartzites" (*Quart. Journ. Geol. Soc.*, vol. lv. p. 657), and Prof. Groom has dealt with the crush-breccias of the Malvern Range (*ibid.*, p. 151).

It has long been felt that some revolution in palæontological nomenclature is needed, and, fortunately, the matter has been taken up boldly and effectively by Dr. Arthur W. Rowe.[1] In old times new species were named from fossils obtained from formations without reference to their special horizons. Some were founded on the evidence of but one or two specimens, and it has not unfrequently happened that "varieties" have been found which preceded in time the type species. Of late years, when increasing attention has been given to careful collecting, there has been a tendency to "make every prominent form a species, on the plea that every minute variation must be ticketed and pigeon-holed." In this way very many of the old land-marks have been removed, the study and identification of species have passed beyond the comprehension of any but the specialist, and the value of his labours to others has been more and more reduced or obscured. Dr. Rowe has now for some years devoted the leisure of a busy life to a careful collection of *Micrasters* from successive stages or zones in the Middle and Upper Chalk. He finds that by examining the facies of the genus in each horizon, passage-forms prove to be the rule, while sharply-defined and typical species are the exception. He has been able to trace an unbroken continuity in

[1] *Quart. Journ. Geol. Soc.*, vol. lv. p. 494.

the evolution of *Micraster*, so that in successive stages of the Chalk he finds variations in the structure of the tests, variations indeed which "are so marked that one can tell by their aid from what zone a *Micraster* is derived." As passage-forms and mutations form the bulk of the genus, it is necessary to mass certain obviously allied forms into groups which will admit of the zoological continuity being exemplified and the zonal peculiarities noted. This is the plan adopted by Dr. Rowe, and it certainly appears most philosophical to take a series of specimens rather than an individual as the foundation for a zonal specific type; and to group rather than to try and separate so many forms. It is satisfactory to learn that the detailed zoological work carried out by Dr. Rowe bears witness to the great value of the palæontological zones which were broadly marked out in the chalk of this country nearly twenty-five years ago by Dr. Charles Barrois.

There is no doubt that the careful collecting of fossils from definite horizons, and from horizons in definite sequence, is of the utmost importance in advancing palæontological knowledge. Such work, as a rule, requires prolonged labour, otherwise the conclusions are worse than useless. Now, by close research, it is possible to trace out the successive modifications that occur in stratigraphic sequence, and this has been attempted with the Graptolites, and with several groups of Mollusca and Brachiopoda, as well as with Echinodermata. Even in so variable a group as the Oysters, it is affirmed by Messrs. R. T. Hill and T. W. Vaughan (*Bulletin* U.S. Geol. Survey, No. 151) that these organic remains possess very distinct specific characters, have definite geologic horizons and are of the greatest value in stratigraphic work. Their value, moreover, may be not merely scientific, but also of some benefit to humanity. Instances have occurred in Texas where, by the aid of these fossils, brought up from great depths in diamond-drill cores, cities upon the point of abandoning the attempt to procure artesian water have been warranted in drilling a few feet farther, and with success.

Views on the duration of geological time have occupied a considerable amount of letterpress during the past fifty years, and during the past few years the subject has been discussed by Mr. G. K. Gilbert, Mr. J. G. Goodchild, Sir A. Geikie, Prof. J. Joly, and Prof. W. J. Sollas.

Mr. Gilbert would look to the influence of precessional changes and to the periodic modification of the climatic conditions of the two hemispheres. Contrasted phases of climate would thus occur every 10,500 years, and such changes should be looked for in the strata. Indications of moist or dry climates, of the increase or decrease of glaciers, and of the local fluctuations of sea-level as affecting the character and extent of strata are the indices to which he would appeal.

Prof. Joly, arguing from the amount of sodium at present contained in the waters of the ocean and the amount annually supplied by rivers, claims that a period of between eighty and ninety millions of years has elapsed since the land first became exposed to denuding agencies. Sodium, as stated by Prof. Joly, is the only dissolved substance of which the ocean has retained substantially the whole amount committed to it by the solvent denudation of geological time.

Prof. Eug. Dubois, dealing with the circulation of carbonate of lime, believes that the real lapse of time since the formation of a solid crust and the appearance of life upon the globe may be more than one thousand million years.

Mr. J. G. Goodchild in 1897 also argued that the more trustworthy data relating to the time of formation of marine strata were furnished by deposits of organico-chemical origin. He concluded that over seven hundred million years would be required since the commencement of the Cambrian period.

Although the conclusions arrived at by investigators are widely at variance, it is not improbable that some trustworthy data may in time be gained by the different methods of research advocated by Gilbert and by Joly. As lately remarked by Sir A. Geikie, progress in geology will be best made by the adoption of more precise methods of research and by a hearty co-operation among geologists in all parts of the world; and Prof. Sollas well observed in his address at Bradford that "our science has become evolutional, and in the transformation has grown more comprehensive." The work of the palæontologist must be supported by very detailed local field-work, work which at present is very much in its infancy. Such work will help in the grand story of "the science of the earth," a story whose materials can only be gathered together by the patient local toiler; while he or she may well be content to see the results worked up by those who by training and opportunity are able to take a comprehensive view of the earth as a whole.

H. B. W.

LORD ARMSTRONG, F.R.S.

THE death of Lord Armstrong on Thursday last, in his ninety-first year, will be regretted in the world of engineering and applied science. To the general public he was best known as a manufacturer of munitions of war, but engineers will remember him more for his developments of hydraulic machinery, and in science his name will be associated with the discussion of the duration of our coal fields, and the development, and discharge phenomena, of statical electricity.

William George Armstrong was born at Newcastle-upon-Tyne in 1810, and educated at a school at Bishop Auckland. He adopted the law as a profession, and became a partner in a firm of solicitors; but a strong bent for scientific pursuits led him to study mechanics with more interest than law and eventually diverted him into another career. Early in life he began investigations of electrical subjects, which resulted in the invention of the hydro-electric machine familiar to all readers of text-books of electricity. The circumstances which suggested this novel electrical machine are well known. The workmen at a colliery near Newcastle had observed that when steam was blowing off from the high-pressure boiler, a smart shock was received if the safety valve was touched, and sparks could be seen. An investigation of the phenomena showed Mr. Armstrong that the boiler was insulated on a dry seating, and the friction of the water particles against the sides of the orifice through which it was escaping caused a development of electricity. On this discovery he based the construction of his hydro-electric machine, which at that time formed the most powerful means of generating frictional electricity. It consisted essentially of an insulated boiler, from which steam at high pressure was allowed to escape through nozzles of peculiar construction. For this he was elected a Fellow of the Royal Society in 1846, while still comparatively a young man.

Another electrical research for which Lord Armstrong will be remembered was concerned with electric movement in air and water, and it culminated in the publication of an elaborate volume on the subject in 1897. In this work a striking experiment, performed with the hydro-electric machine half a century earlier, was made the starting-point of a valuable research on the nature of electric discharges. Two glasses of distilled water were placed near together, and a thread of cotton, which was coiled up in the one, had its free end placed so as to dip in the other. On negatively electrifying the glass of

water in which the cotton was coiled, and the other glass positively, the thread crept out of its glass into the other, while a stream of water passed in the opposite direction. This and other evidence led Lord Armstrong to conclude that an electric current consists of a negative stream flowing in one direction surrounded by a sheath of positive stream flowing in the opposite direction. The theory presents difficulties which have not been overcome, but neglecting it altogether, the photographs published to illustrate it are the most remarkable examples of electric discharges ever produced.

To Lord Armstrong the world is indebted for the development of the hydraulic machinery which to-day plays so important a part in the business of our docks and large railway stations. He first invented the hydraulic crane, and, between 1845 and 1850, the accumulator by which an artificial head of water is substituted for the natural head. By this invention hydraulic machinery was rendered available in almost every situation. Being very convenient where power is required at intervals and for short periods, it has come into extensive use for working cranes and hoists, opening and shutting dock gates, turning capstans, raising lifts, &c., and in many cases has procured important economies, both as regards time and money, at harbours and railway stations where large amounts of traffic have to be dealt with. In the Navy, again, its applications are almost infinite in number. In awarding the Albert Medal to Lord Armstrong in 1873, the Society of Arts recognised the benefits which have accrued to manufactures through his development of the hydraulic transmission of power.

For the manufacture of hydraulic machinery the Elswick Engine Works was founded, and there, in 1854, was constructed the first rifled ordnance gun that bears the name of Armstrong. Its trials were so satisfactory as regards range and accuracy that it was soon adopted by the Government, and Armstrong was appointed engineer of rifled ordnance, being made C.B. and receiving the honour of knighthood. Under his supervision some 3500 of these guns were turned out between 1859 and 1863, and England became the possessor of the best armament then in existence.

In 1863, Sir William Armstrong resigned his official appointment, and rejoined the Elswick Manufacturing Company, and in the same year he was president of the meeting of the British Association at Newcastle-upon-Tyne. In that capacity he drew attention to the gradual lessening of our supply of coal, and the prospects of exhaustion of our coalfields. The discussion suggested by this address led to the appointment of a Royal Commission to inquire into all the circumstances connected with the national coal supply, and he was nominated a member of it. The better utilisation of natural forces was a subject to which he again called attention in his presidential address to the mechanical science section of the Association at York in 1881, when he commented upon the wastefulness of the steam engine, and discussed the question whether its difficulties might be avoided by resorting to electrical methods of obtaining energy.

Lord Armstrong received many honours. Cambridge made him a LL.D. in 1862 and Oxford a D.C.L. in 1870. He was president of the Institution of Civil Engineers in 1882, and he more than once served the same office in the Institution of Mechanical Engineers. An original member of the Iron and Steel Institute, he was in 1891 awarded the Bessemer Medal by that body, and the large number of foreign decorations which were bestowed upon him attested the reputation which his work won for him abroad. His presidency of the Newcastle Literary and Philosophical Society was the occasion for several noteworthy addresses, and he wrote a number of articles, pamphlets and short treatises on scientific subjects. His public spirit and philanthropy are justly appreciated in Newcastle. A lecture hall for the Literary and Philosophical Society, an operating theatre for the Infirmary, thousands of pounds towards the restoration of a fine old steeple, other thousands to the Children's Hospital, three-quarters of a 20,000*l*. bridge across Benton Valley, 10,000*l*. to the Natural History Museum, a Mechanics' Institute, and schools for the Elswick men, a banqueting hall, public parks—these were among his gifts to the city.

For these works, as for his contributions to the progress of science and industry, his name stands high among the great men of the century.

WILLIAM POLE, F.R.S.

MR. WILLIAM POLE, F.R.S., whose death occurred on December 30, at the age of eighty-six, was distinguished both as an engineer and as a musician. He was born in Birmingham in 1814, and, after following the profession of engineering for some years, was appointed professor of civil engineering in Elphinstone College, Bombay. In 1847 he returned to London, devoting his chief attention to the mechanical branch of his profession, and soon became a recognised authority on engineering matters Between 1859 and 1867 he was professor of civil engineering at University College, London, and lecturer at the Royal Engineer Establishment, Chatham. He served on the Council of the Institution of Civil Engineers from 1871 to 1875, in which year he was appointed honorary secretary.

Mr. Pole's services to the Government in carrying out scientific work of various kinds were very important. In 1861–1864 he was a member of the committee on iron armour, and from that year till 1885 he was almost constantly employed by the Government in one of its departments, bringing the knowledge of an expert to bear on questions differing so widely as the comparative merits of the Whitworth and Armstrong systems of artillery and the gas and water arrangements of the metropolis. He acted as secretary to four Government commissions of inquiry—namely, from 1865 to 1867 to the Royal Commission on Railways, from 1867 to 1869 to the Royal Commission on Water Supply, from 1882 to 1884 to the Royal Commission appointed to inquire into the pollution of the Thames, and in 1885 to a committee on the science museums at South Kensington. From 1871 to 1883 he was consulting engineer for the Imperial railways of Japan, and on his retirement the Mikado decorated him with the Imperial Order of the Rising Sun.

In June, 1861, Mr. Pole was elected a Fellow of the Royal Society of London, and was vice-president in 1876 and 1889. He was elected into the Royal Society of Edinburgh in 1877, and into the Athenæum Club as a man of "distinguished eminence in science," in 1864. He published in 1844 a quarto treatise on the steam engine; in 1848 a translation of a German work on the same subject; in 1864 and 1870 "Scientific Chapters in the Lives of Robert Stephenson and I. K. Brunel"; in 1872 a treatise on iron; in 1877 he wrote the life of Sir William Fairbairn, and in 1888 that of Sir William Siemens. He was also the author of a well-known scientific work on the game of whist, and contributed a number of papers to scientific journals and periodical literature.

Mr. Pole was skilled both in the theory and practice of music. He took the Oxford degree of Bachelor in 1860, and in 1867 that of Doctor of Music. He also held for some years the office of examiner in music at the University of London. He was the author of "The Philosophy of Music," "The Story of Mozart's Requiem," and other compositions.

NOTES.

SCIENCE is represented in the list of New Year's honours by Sir William Turner, F.R.S., professor of anatomy in the University of Edinburgh, who has been made a K.C.B. Other names familiar in various branches of the scientific world are:—Dr. Thomas Barlow, physician extraordinary to the Queen, and Dr. W. S. Church, who have each received the dignity of a baronetcy; Mr. Hiram Maxim, the well-known inventor, has been knighted; Mr. F. Victor Dickins, Registrar to the University of London, and Lieut.-Colonel G. T. Plunkett, director of the Department of Science and Art, Dublin, have been appointed to the Order of the Bath (C.B.); and Captain F. E. Younghusband, known for his journeys in China and India, has been granted the Kaiser-i-Hind medal.

THE *Times* of Tuesday, December 25, contains an article on the dispute between the London United Tramways Company and the managers of Kew Observatory. It is written very much from the point of view of the Tramways Company, and contains several misstatements to which Prof. Rücker calls attention in a subsequent letter. The question, as Prof. Rücker rightly points out, is not whether it is possible to obtain "perfect" insulation, but whether the insulation, which every one knows can be obtained, should not be insisted upon when the interests of so valuable an institution as Kew Observatory may be preserved by doing so. The engineers of the Tramways Company originally proposed to limit the maximum potential difference between the rails and earth to one-fifth of a volt, a condition which was accepted by Kew, but they have since found that, by the system they proposed to adopt, they are unable to keep within this limit. There are, however, other systems which could be used, and it rests with the Board of Trade to decide whether some other system should be adopted or not. It is to be hoped that the final decision will enforce everything being done that can be done to prevent interference with the very important magnetic work carried on at Kew, or, if protection is considered impossible, that adequate compensation will be insisted upon. Quite apart from the particular point at issue, it is an anachronism which ought to be remedied as quickly as possible that electrical engineers should be allowed to let their waste current flow into the soil. The evils of the system are apparent in many instances already; they will become intolerable when electric traction is developed on a large scale in London.

AT the fourth International Zoological Congress, held at Cambridge in 1898, it was decided that the fifth Congress, in 1901, should be held in Germany; the selection of the town and president being left to the German Zoological Society, acting in conjunction with the Permanent Committee of the Zoological Congress at Paris. Announcement has now been made that the meeting place will be Berlin, on Aug. 12–16, and the president Prof. K. Moebius, director of the zoological collection of the Natural History Museum, with Prof. F. E. Schulze, director of the Zoological Institute, as vice-president. The secretaries of the Congress will be Herr P. Matschie, Dr. M. Meissner and Dr. R. Hartmeyer. The treasurers will be Herr H. Schalow and Herr Otto Stutzbach. Arrangements as to meetings and papers will be in charge of Prof. L. H. Plate, apartments and receptions will be under the care of Dr. L. Heck, and the lighter pleasures of the meeting will be managed by Dr. O. Jaekel. The meetings will be held in the Natural History Museum and neighbouring rooms of the University. Among the subjects to be brought before the Congress are the following:—Fossil remains of man, Prof. Branco (Berlin); vitalism and mechanism, Prof. Bütschli (Heidelberg); theories of fertilisation, Prof. Yves Delage (Paris); the psychological attributes of ants, Prof. A. Forel (Morges); the malarial problem from a zoological point of view, Prof. Grassi (Rome); mimicry and natural selection, Prof. E. B. Poulton (Oxford). After the conclusion of the Congress an excursion will be made to Hamburg for the purpose of visiting the Natural History Museum and Zoological Garden there, and also to Heligoland. Communications concerning the Congress should be made to the president, 43, Invalidenstrasse, Berlin, N. 4. Admission to the Congress will be free to all zoologists and all friends of zoology.

IN connection with the remeasurement of the Peru arc of meridian by a French Commission, M. F. Gonnessiat, of the Lyons Observatory, has been appointed director of the Observatory at Quito for a period of five years.

THE committee of the U.S. House of Representatives in charge of the Bill to substitute, in 1903, the metric system of weights and measures for the common system in use, has reported in favour of the change, and there is reason to believe that the Bill will become a law.

IT has been found necessary to postpone the opening of the Exhibition of Modern Illustration in the Indian Section (Imperial Institute Road) of the Victoria and Albert Museum, from January 7 until January 14. The Exhibition will be open free every day, and will remain open about three months.

AT the annual meeting of the Geographical Association on January 9, at the College of Preceptors, Mr. Douglas W. Freshfield, president of the Association, will show a series of lantern slides illustrating his recent journey in the Sikhim and Nepalese Himalaya.

WE are informed that the inaugural meeting of the Birmingham Local Section of the Institution of Electrical Engineers will be held in the buildings of the Birmingham University at 8 p.m., on Wednesday, January 23. Dr. Oliver Lodge, the chairman of the Section, will then deliver his address. The president and secretary of the Institution have accepted an invitation to be present.

WE learn from *Science* that Mr. D. O. Mills, of New York, has promised the University of California about 24,000 dollars, to defray the expenses of a two years' astronomical expedition from the Lick Observatory to South America or Australia, with the object of studying, under good conditions, the movements of stars in the line of sight.

THE monthly record of anthropological science, which has just appeared under the title of *Man*, ought to prove an excellent recruiting agent for the Anthropological Institute, under the direction of which it is published. The first number contains several articles and reviews on anthropology understood in its widest sense, and provides all who are interested in the study of man with a *précis* of important contributions to various branches of the science. A coloured picture of a Buddhist wheel of life from Japan forms a frontispiece, and is described by Mr. N. W. Thomas.

THE death of Major Serpa Pinto, the African explorer, is announced from Lisbon. He was leader of an expedition organised by the Lisbon Geographical Society and the Geographical Commission of the Ministry of Marine, for the purpose of exploring the hydrographical conditions between the basin of the Congo and that of the Zambesi, and generally to explore the whole region between the provinces of Angola and Mozambique. The expedition started from Benguella in November, 1877, and reached Durban in 1879. Little new country was opened up by the journey, as Africa had previously been crossed by Livingstone and other explorers. His contributions to a knowledge of the hydrography of the country between the coast and the Kwando were, however, of importance, and he was able to describe the large tableland that characterises

a considerable part of this region. The expedition was well supplied with scientific instruments, with which numerous observations that have been serviceable to the cartographer and the meteorologist were taken. The Royal Geographical Society awarded him their Founder's Medal for this journey. His travels from Mozambique in 1884, and into the Shiré country in 1889, were of political importance, but have no scientific value.

SIR HARRY JOHNSTON has sent to the Royal Geographical Society an account of his recent journeys in the Uganda Protectorate, and it is here abridged from the *Times*. He succeeded in making very interesting natural history collections in that part of the Congo Forest which stretches from the basin of the Ituri River to the vicinity of the Semliki. Many photographs were taken of the dwarfs, male and female, of their dances, implements and dwellings. Anthropological measurements were also made by Mr. Doggett, the collector accompanying the Special Commissioner's expedition. Other dwarfs were subsequently examined from the Mboga district, which is that outlying portion of the Uganda Protectorate which lies to the north-west of the Semliki River. It was found that (as other travellers relate) the dwarfs were of two types—black-skinned, with a good deal of stiff, curling black hair about the body, and red or yellow-skinned, with a tendency to redness in the hair of the head and yellowish-grey in the hair growing on the body. Some of the dwarfs, especially when young, have quite hairy bodies, and their women not infrequently have incipient whiskers. These Congo dwarfs no longer speak an original language of their own, but talk, in a slightly corrupted form, the language of the taller negroes in whose vicinity they dwell. Amongst physical features which specially distinguish them from their neighbours is the large size and flatness of the nose. This organ has scarcely any bridge, and the wings of the nose are very large. The dwarfs also have a very long upper lip, which is scarcely, if at all, erected. In many other points they exhibit ape-like features, but their intelligence is, as a rule, well developed, and though hideously ugly and often very ape-like in appearance, they are usually of a winning and cheerful disposition, while their dances are so frolicsome and gay and full of pretty movements as to distinguish them markedly in that respect from the average negro.

SIR H. JOHNSTON has ascertained that there exists in these Congo forests a remarkable species of horse or zebra not hitherto known or described. According to his observations, the gorilla as well as the chimpanzee exists in these Congo forests between the Ituri and the Aruwimi. He hopes to send home a specimen of the chimpanzee which is found in the western part of the Uganda Protectorate. Sir H. Johnston devoted three weeks to examining the upper part of Mount Ruwenzori. He and two of his companions ascended to a higher point, seemingly, than has yet been reached by any explorer. Beyond an altitude of 14,800 feet a succession of sheer walls of rock was found, the ascent of which was extremely difficult. Snow was found lying as low as 13,000 feet, and permanent snow was reached at 13,500 feet. A large botanical collection was made, and photographs were taken of the more remarkable forms of vegetation, which include two species of giant lobelia, a tree-heath grown to 50 feet, and the tree groundsel which was discovered by Sir H. Johnston in 1884 on the upper parts of Kilima-Njaro. Collections in zoology made on the mountain in this vicinity will probably result in at least one new species of monkey, a new hyrax, a new antelope, and a number of birds, reptiles and insects new to science.

DURING the past week this country has been visited by a series of severe storms, which have caused much damage to both life and property. On the morning of Thursday, December 27, the Daily Weather Report issued by the Meteorological Office showed that a "V" shaped depression lay over St. George's Channel, the distribution of barometric pressure being of a complex character, with high readings over both the north and south of Europe. During the day the depression moved eastwards across England, but was followed very closely by a new and much deeper disturbance. The centre of this storm passed across the northern parts of Ireland and England on December 27 and 28, and on the morning of the 29th the centre lay over Denmark, having travelled during some part of its course at about 23 miles an hour, while the velocity of the wind in the vortex reached over 80 miles an hour; at Greenwich the pressure anemometer registered 27 lbs. on the square foot in the afternoon of December 28. A further disturbance moved along our south coasts on the 30th and 31st, and occasioned northerly gales over a large part of England, during which some heavy falls of rain, amounting to 1—3 inches, were recorded in several parts of the country, resulting in disastrous floods.

THE report of the Meteorological Council for the year ending March 31, 1900, has recently been presented to Parliament. The principal changes during the year have been the appointment of Mr. W. N. Shaw as secretary, in succession to Mr. Scott, retired, and the appointment of Captain Campbell Hepworth, R.N.R., as marine superintendent, in place of Lieut. Baillie, deceased. The appendices contain (1) regulations for superannuation allowances to the established clerks, (2) correspondence referring to the continuation with the National Physical Laboratory of the relations hitherto subsisting between the Meteorological Office and Kew Observatory, and (3) further correspondence with H.M. Treasury and the Scottish Meteorological Society relating to the maintenance of the Ben Nevis observatories. A comparison of the evening weather forecasts (which appear in the morning newspapers) shows that the percentage of complete and partial success during the year amounted to 82. The success of the storm-warning telegrams issued to the sea coasts was even more gratifying, amounting to 91 per cent., while the warnings not justified by subsequent weather were only 4·8 per cent. The report contains an account of anemometer experiments made at Holyhead, and a note upon investigations in atmospheric electricity.

MANY years ago, a paper was published by H. Arons, dealing with the symmetry of crystals as deduced from their elastic potentials, in which it was shown that if a crystal possessed two planes of symmetry, then either the angle between the planes is 45°, 60°, or 90°, or every plane through their intersection is a plane of symmetry. In the *Atti dei Lincei*, ix., 10, Signor C. Viola now discusses the various forms of crystalline symmetry with reference to the so-called "law of rationality of the indices," and raises objections to this law. From considerations partly based on observation, partly on the theory of elasticity, Signor Viola gives a proof of the theorem that there are thirty-two different possible kinds of crystalline symmetry.

A METHOD of crystallising substances from albuminous solutions without the formation of a crust on the surface is described by Herr A. Wróblewski in the *Bulletin* of the Cracow Academy, viii., 1900. The method consists in confining the solution to be crystallised in a tube with a parchment bottom, and depends on the fact that evaporation takes place through the parchment although the surface exposed to the air shows no signs of moisture from the transpiration of the liquid. The apparatus which the author describes has enabled him to obtain crystals of albuminous substances of greater purity than those resulting from the use of Hoffmeister's method, and, moreover, it suggests several interesting experiments connected with osmotic phenomena.

IN his address on the future of anatomical teaching, delivered before the Middlesex Hospital Medical Society on October 18, and published in the December number of the Middlesex Hospital *Journal*, Prof. Alexander Macalister urges that much of the matter in our anatomical text-books might advantageously be omitted from what is taught to the over-burdened student. The essential thing for the future practitioner to learn is the position of the working parts of the human frame which affect his practice. In the case of the shoulder-girdle, for instance, he must know the precise shape of the articular surfaces, their extent of motion, where they are covered with muscle, and where the capsule is thinnest. But the minute description of the ligaments do not concern him. Neither need he know the relations of minute arteries in other parts of the body, or be taught the homology of, say, the human pterygoid bones. Not that what used to be called transcendental anatomy is decried by the professor. On the contrary, the importance of its study is extolled; but the ordinary medical student has not the time for it.

WE have received a paper by Messrs. D. S. Jordan and J. O. Snyder on fishes recently collected in Japan by Mr. Otaki and the U.S. steamer *Albatross*, published in the *Proceedings* of the U.S. Museum (vol. xxiii., pp. 335–380). Fourteen new species are described, several of which are referred to new generic types.

In the section of the *Papers* from the Harriman Alaska Expedition devoted to Diptera, Mr. D. W. Coquillet describes a considerable number of new forms, among them being a new genus —Ornithodes—of Tipulidæ. This most remarkable discovery is, however, the existence in Alaska of a species of Telmatogeton, a genus previously known only from St. Paul's Island in the Indian Ocean.

THE issue of the *Notes* from the Leyden Museum for January and April last (published in July and received a few days ago) opens with a communication from Mr. M. C. Piepers, in which the views advanced by him at the Cambridge Zoological Congress in regard to the evolution of colour in butterflies are defended against the criticisms of Miss Newbigin and others. The author urges that none save those who have made the morphology of the Lepidoptera their special study are capable of fully appreciating, much less of criticising, his views.

A SECOND article in the same issue, by Dr. F. A. Jentink, describes a remarkably coloured stoat in the Leyden Museum. After describing the gradual change from the brown summer to the white winter coat in the species and *vice versâ*, the author goes on to say that the example in question is striped in such a curiously symmetrical manner that it might well be regarded at first sight as representing an unknown species. The brown of the upper parts is locally interrupted by narrow bands of longer white hairs, which appear to be the remnants of the winter coat; and there are patches of white elsewhere—notably a ring dividing the black tip of the tail from the brown of the remainder of that appendage. The specimen was killed in Holland during the spring of 1869.

THE Geological Survey of Canada has published a useful general index to the reports of progress, 1863 to 1884. Since 1884 the successive annual reports have been separately indexed, but it is intended at a later date to prepare a general index to them. The volume before us, which contains full references to subjects, localities and authors, has been compiled by Mr. D. B. Dowling.

CRAGS of weathered granite in the Black Hills of South Dakota are described and pictured by Mr. E. O. Hovey (*Bull.* Geol. Soc. Amer., vol. xi). The granite is intrusive in the mica-schists of the region, but the schists have suffered most from erosion, so that the granite, which is intersected by numerous joints, stands up in places in sharp pyramidal and needle-like forms.

THE latest addition to Prof. Penck's *Geographische Abhandlungen* is a pamphlet on the three lakes of the Reschen-Scheideck, by Prof. Johann Müllner. The positions of the lakes, their supply areas, depths, surface levels, rainfall conditions and ice-covering, are dealt with in separate chapters, and besides the interest of its results the investigation forms another excellent example of the adequacy of the geomorphometric methods employed by the geographers of the Vienna school.

THE third number of the current volume of the *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* is devoted to a review of the present state of knowledge of the geographical distribution of plants and animals, by Dr. Arnold Jacobi. The special problem dealt with is the position and form of biogeographical regions, and the bases on which such regions must be defined. A general map of animal distribution and special maps showing the distribution of the jay and the bullfinch accompany the paper.

THE November number of *La Géographie* contains the first part of a paper on the geography of the coast-region of the Landes, by M. Hautreux, well known for his work on the oceanography of the Bay of Biscay. M. Hautreux here discusses the wind records from a number of coast stations, with special reference to their influence on ocean currents and on the formation and movement of sand dunes. We note with satisfaction, from an announcement also in *La Géographie*, that the efforts of M. Hautreux during the last twenty years have borne fruit in the establishment of a "Société d'Océanographie du Golfe de Gascogne," to which we wish every success.

WE have received a copy of an official pamphlet on the currents of the Gulf of St. Lawrence, practically an abstract of the reports on surveys of tides and currents for the seasons 1894, 1895 and 1896. The information is arranged in a form likely to be specially useful to navigators; the surface currents in each locality are minutely described, and the causes of the general circulation in the Gulf are dealt with separately. One of the most important facts brought to light by the work of the survey is that no confirmation is forthcoming of the supposition that a current enters the Gulf by Belle Isle Strait and leaves it by Cabot Strait. The current flowing out by Cabot Strait apparently consists partly of water from the St. Lawrence and partly of water entering Cabot Strait itself on the eastern side.

THE November number of *Petermann's Mitteilungen* contains the third and last instalment of an important paper by Dr. L. Frobenius on the "Kulturformen" of Oceania. Dividing the region into four parts, in the west "Indonesia" or Farther India, in the south-east Australia, east Melanesia, and north-east Mikronesia, the author points out that there are three main lines extending from the first of these eastwards, a southern axis towards Australia, a central axis just skirting Australia, and a northern axis through the Mikronesian archipelago. To the civilisation of the southern axis the name "nigritic" is given, to that of the central axis "vormalaysian," and to that of the northern "malayo-asiatic." The paper is illustrated by an elaborate series of maps.

PROMPTITUDE of publication is now the distinguishing characteristic of the *Journal* of the Chemical Society. The January number of the journal contains the Rammelsberg Memorial Lecture (pp. 43) delivered by Prof. H. A. Miers, F.R.S., on December 13.

THE third volume of Prof. G. O. Sars's detailed "Account of the Crustacea of Norway" has been published by the Bergen Museum. It treats of the Cumacean group of Crustacea, which

is but imperfectly known; and it will be of service, not only for the determination of Norwegian species, but also for the future investigation of the Cumacean fauna of other countries.

DURING January, the following popular science lectures will be delivered at the Royal Victoria Hall, Waterloo Road:—January 8, History of the Solar System, Mr. F. Womack; January 15, Sea Coasts of Britain, Prof. H. G. Seeley, F.R.S.; January 22, Waves and Oscillations Mr. F. W. Porter; January 29, Niagara Water Power Installation, Prof. Capper.

THE Bath Natural History and Antiquarian Field Club has sent us a copy of its *Proceedings* (vol. ix. No. 3), containing among other contributions, a reduced copy of an old map of the Parish of Walcot, made in 1740. Then the parish was a little country village, now it is a great suburb of Bath. The notes on this map, by the Rev. C. W. Shickle, are of sufficient interest to make one wish they had been more extensive.

WE have received the November number of the *Victorian Naturalist*, the journal and magazine of the Field Naturalists' Club of Victoria. It is illustrated by some good views of the Basalt columns of Sydenham, and contains a variety of notes on local natural history.

IN the last number of the *Berichte der Deutschen Chemischen Gesellschaft* (33, 3307) Herr E. Buchner describes new experiments the results of which must be regarded as strong evidence in favour of the view that the active agent in fermentation processes is of enzymic character. Quantities of yeast were dried in vacuo at temperatures from 35°—100° C, and then heated for several hours in a current of hydrogen at 100° and then at 110° C. After this treatment the yeast has no fermenting power, as was conclusively proved by observations of its action on wort, the observations extending over a period of three weeks. The sterile yeast was then ground up into a paste with sand, kieselguhr and 10 per cent. aqueous solution of glycerin, and the mass subjected to strong hydraulic pressure. The liquid pressed out from the paste was found to have strong fermenting action. In spite of the sterilisation and the loss involved in the extraction with aqueous glycerine, the fermenting power was found to be one-quarter to one-half that of the original yeast. These experiments do not conform to the hypothesis set up by the opponents of the enzyme theory, that the fermenting power of press yeast is due to living protoplasm, for the latter is certainly no longer present in the yeast after its subjection to the sterilising process described. The specific action of the enzyme zymase is therefore not dependent on the presence of the living cell, and in this respect zymase is perfectly analogous to the active enzyme of urea fermentation isolated by Miquel.

THE additions to the Zoological Society's Gardens during the past week include a Derbian Zonure (*Zonurus giganteus*) from South Africa, presented by Major J. W. Jerome; three Bengal Monitors (*Varanus bengalensis*), a Conical Eryx (*Eryx conicus*), an Indian Eryx (*Eryx johni*) from India, deposited; two Bar-tailed Pheasants (*Phasianus reevesi*) from North China, twelve European Tree Frogs (*Hyla arborea*), European, purchased.

OUR ASTRONOMICAL COLUMN.

HELIOMETER MEASURES OF h AND χ PERSEI.—The great care taken and accuracy obtained by Prof. Wilhelm Schur in his observations with the fine Repsold heliometer of the Göttingen Observatory, make one regard the publications of the "Astronomische Mittheilungen von der Königlichen Sternwarte" as so many standard illustrations of heliometer reductions. The sixth part of this publication deals with the two bright star clusters, h and χ, in the constellation of Perseus. Both of these clusters have been measured before, the first by Krüger with the Bonn heliometer, by Bredichin with the micrometer, and by Karl Oertel with the large München refractor; and the latter by Vogel with the Leipzig 8-inch refractor, Pihl with the micrometer, and by Lohse and Bronsky and Stebnitzky from photographs. Prof. Schur compares his results with all these previous measures.

For his triangulation, Prof. Schur has used fifteen of the brighter stars in the two clusters; no less than 61 different distances have been measured, each distance having been determined on three, but generally more occasions. We must, however, simply restrict ourselves to the result of the whole investigation, which has led Prof. Schur to give the following final places for the stars he has employed; the consecutive alphabetical letters in the first column refer to the notation he has adopted in the chart of the region accompanying this publication. In the following summary the secular variation and proper motions have been omitted, and Kr. in the fourth column refers to Krüger's magnitudes:—

Positions of 15 *Stars in the Clusters h and* χ *Persei for the Epoch* 1893.75, *and Equinox* 1890.0.

This triangulation will form a fine groundwork for future photographs of the fainter stars in this region, for the constants for the reduction of the plates can be determined by the heliometer positions of the brighter stars. The great value of heliometer measures as forerunners of the photographic plate is a point that cannot be overlooked when dealing with star clusters, nebulæ immersed in stars, or *vice versâ*.

ANNUAIRE POUR 1901 BUREAU DES LONGITUDES.—This useful annual, issued under the direction of MM. Janssen, Cornu and Lœwy, is compiled in similar manner to previous issues. A complete calendar, with the usual solar and lunar data, lists of celestial phenomena for the year, comprising occultations, eclipses, maxima and minima of variable stars, elements and ephemerides of the planets, shooting stars, &c., occupy some three hundred pages. An important notice is issued stating that all the times given in the volume are expressed in *civil mean time*, reckoned from 0h. to 24h., commencing at midnight.

A lengthy appendix is occupied by a dissertation on the electrical transmission of power, by M. Cornu, and other articles are contributed by M. Poincaré (Revision of the Meridian Arc of Quito); M. Lœwy (Astronomical Conference at Paris); M. Bassot (Foundation of the Metric System); M. B. de la Grye (International Geodesy), and M. Janssen (Work at the Observatory on Mont Blanc).

CATALOGUE OF STARS.—The sixth volume of the publications of the Hamburg Observatory consists of the reduced places of stars between 80° and 81° north declination, determined with the Repsold meridian circle of 10·8 cm. aperture and 1·62 metres focus. The stars are arranged in 69 zones, an index being furnished to show the various zones containing each object.

NEW MINOR PLANETS.—A telegram through Laffan's Agency from New York, dated January 1, says:—Mr. W. R. Brooks has discovered by means of photographs three new planets within one degree of Eros. The brightest is somewhat brighter than Eros.

SPAIN AND GREENWICH TIME.—After midnight of the 31st of December last, Spain began the new century by adopting officially throughout the country Greenwich time, the hours being numbered one to twenty-four.

THE USE OF BLAST-FURNACE GASES IN GAS ENGINES.

DURING the past year all the difficulties in the use of blast-furnace gases have successfully been overcome, and it is interesting to consider the rapid progress that has been made in this important development of metallurgical practice. The question was first taken up by Mr. B. H. Thwaite in 1894, and a 15 horse-power engine, worked by blast-furnace gas purified by his apparatus, was set to work at Wishaw, in Scotland, in February 1895. Since that date numerous small motors have been in operation in this country using purified blast-furnace gas driving machinery and dynamos. In the development of large motors and in their adaptation to blowing engines Belgium has taken the lead. In May 1898, Mr. A. Greiner, of the Cockerill Company, described a 200 horse-power engine in successful use at his works. The results attained stimulated experiment in Germany and in Luxemburg. The Cockerill Company, however, continued to take the initiative by starting, on November 2, 1899, the largest gas engine ever built. On May 9, 1900, Mr. Greiner described the engine to the Iron and Steel Institute, and gave the results of six months' working. This was the first gas engine to run the blowing engine of its own furnace. Results of tests of this gas engine, by Prof. Hubert, of Liége, are given in an appendix to an exhaustive paper on power gas and large gas engines, read by Mr. H. A. Humphrey before the Institution of Mechanical Engineers on December 14, 1900. The engine was designed by Mr. Delamare-Deboutteville, and built by the Cockerill Company. It is a single cylinder 600 horse-power engine, working on the Otto cycle, and direct coupled to a double-acting blowing cylinder. The large engine and blower shown by the Cockerill Company at the Paris Exhibition was a duplicate of the one under discussion. It was rated at 700 horse-power on blast-furnace gas, at 800 horse-power on producer gas, and at 1000 horse-power on illuminating gas. In an exhaustive paper on the subject, published by Prof. Joseph W. Richards in the current number of the *Journal* of the Franklin Institute of Philadelphia, the following list of blast-furnace gas engines now in operation is given:—

	No.	Horse-power.
Seraing, Belgium	4	500
Differdingen, Luxemburg	4	500
Hoerde, Westphalia	2	600
	2	1000
Friedenshütte, Silesia	2	200
	2	300
Oberhausen	1	600
Dudelingen	2	600
	2	1000
Kneutingen	2	500
Roechling	1	200
	2	600
Ruhrort	1	500
Barrow, England	—	1000
Toula, near Moscow	3	600
	3	200
Island of Elba	—	1000

The Cockerill Company is now constructing, for the Roechling Ironworks in Lorraine, three 1200 horse-power gas engines. They are double-cylinder tandem engines directly attached by a tail rod to the blowing cylinder. The Cockerill Company and Mr. Delamare-Deboutteville have now decided to build engines of 2500 horse-power. They will have two tandem cylinders on each side of the dynamo, giving four cylinders per engine. They are designed for a central electric station.

In view of the remarkable results already attained, there can be no doubt that during the next few years the design and erection of large central power-stations for the generation and distribution of electric energy in bulk will be one of the most important problems with which engineers will have to deal. The new stations will be larger than any now existing, and every possible effort will be made to reach an unprecedented degree of economy in the production of power. Mr. Humphrey's paper strongly urges the claims of the gas engine to rank as a rival of the steam engine for large power units. The results of a trial of a 400 horse-power Crossley gas engine carried out by Mr. Humphrey are certainly most satisfactory, whilst its capability for continuous work has been shown at Messrs. Brunner, Mond and Co.'s works at Winnington, Cheshire, where it is used for their electrolytic plant. The employment of gas engines in large central station work is, however, still very limited, for out of the total of seven central stations where gas motors are used, the largest has only an aggregate of 650 horse-power, whilst the largest unit is of only 200 horse-power. The use of the waste gases from blast furnaces renders it possible to have a supply of cheap fuel. This result can also, according to Mr. Humphrey, be attained by the use of a Mond producer plant, which is suitable for converting cheap bituminous fuels into suitable gas for gas engines, and at the same time permits of the recovery of the ammonia from the coal as a by-product.

The great industrial revolution which is imminent in the economical utilisation of blast-furnace gases is best shown by the careful calculations made by Prof. Richards of the results that would be attained by the application of this improvement to American blast-furnace practice. As an illustration of average practice, he takes the figures from a blast-furnace plant in Eastern Pennsylvania, which is making in three furnaces 2600 tons of pig iron per week. The composition of the gas by volume is as follows:—

CO_2	CO	H	N
9	27	1·8	62·8

The pig iron produced daily is 370 tons; the fuel used per 100 kilograms of pig iron, 100·0 kilograms; carbon in fuel, 82·9 kilograms: carbon in flux, 4·6 kilograms; carbon in the iron, 3·1 kilograms; efficiency of stoves, 60 per cent.; efficiency of boilers and engines, 4·5 per cent.; pressure of blast, 1·3 kilogrammes per square centimetre (20 lbs. per square inch); and temperature of blast 555° C.

With these conditions, the calculations are as follows:—

Calorific power of gas per cubic metre, 873 calories; volume of gas per 100 kilograms of pig iron, 434·7 cubic metres; calorific effect of gas per 100 kilogrammes of iron, 379,490 calories; heat required to heat blast per 100 kilograms of iron, 90,500 calories; indicated horse-power of engines for blast, 950 horse-power; indicated horse-power of engines for hoist, pumps, &c., per 100 tons of iron daily, 65 horse-power.

From these calculations the following conclusions are arrived at:—

		Calories.
Calorific effect of gases per 100 kg. of pig iron		379,490
Lost (10 per cent.)	37,950	
For heating blast	90,500	
		128,450
Surplus for burning develops ...		251,040
Surplus per 100 tons of pig iron daily		251,000,000

The horse-power at 100 per cent. efficiency would be 16,400; horse-power with steam at 4½ per cent. efficiency, 738; deficit of steam power per 100 tons of iron daily, 277 horse-power; horse-power with gas engines at 30 per cent. efficiency, 4920; surplus power with gas engines per 100 tons daily, 3900 horse-power; deficit of steam power per 370 tons daily, 1025 horse-power; surplus of gas engine power per 370 tons daily, 14,400 horse-power.

It is an actual fact that at the works considered by Prof. Richards the three blast furnaces are charged with 800 horse-power, furnished to them by the boiler plants fired by coal. It is also a fact that nearly 10,000 horse-power is raised for the rest of the plant by coal-fired boilers, and that all of this could be supplied by gas engines utilising the blast-furnace gases. The saving in the coal bill alone would amount to at least 30,000*l.* in one year. The gas-engine plant to accomplish this would cost 100,000*l.* These calculations, based on average practice, bring out very clearly the great saving of power possible by the economical utilisation of blast-furnace gases.

PRIZES PROPOSED BY THE PARIS ACADEMY OF SCIENCES FOR 1901.

THE following prizes are offered by the Paris Academy of Sciences for the year 1901:—

In Geometry, the Francœur Prize (1000 fr.), for discoveries or works useful to the progress of the mathematical sciences, pure or applied; the Poncelet Prize (2000 fr.), with similar conditions; and in Mechanics, the Extraordinary Prize of 6000 francs, for progress tending to increase the efficiency of the French naval forces; the Montyon Prize (700 fr.); the Plumey

Prize (2500 fr.), for improvements in steam engines or any other invention which contributes to the progress of steam navigation; and the Fourneyron Prize (500 fr.), for a theoretical or experimental study of steam turbines.

In Astronomy, the Lalande Prize (540 fr.), for the best work tending to the advancement of astronomy; the Valz Prize (460 fr.), for the most interesting observation during the current year. In Physics, a La Caze Prize (10,000 fr.); the Gaston Planté Prize (3000 fr.), for a discovery, invention or important work in the field of electricity; and the Kastner-Boursault Prize (2000 fr.), for the best work on the applications of electricity in the arts, industry and commerce. In Statistics, a Montyon Prize (500 fr.). In Chemistry, the Jecker Prize, and a La Caze Prize (each of 10,000 fr.), for researches in chemistry. In Mineralogy and Geology, the Delesse Prize (1400 fr.). In Physical Geography, the Gay Prize (2500 fr.), for a study of the distribution of alpine plants in the mountains of the Old World. In Botany, the Bordin Prize (3000 fr.), for a study of the influence of external conditions upon the protoplasm and nucleus in plants; the Desmazières Prize (1600 fr.), for a study of cryptogams; the Montagne Prizes (1000 fr. and 500 fr.), for researches on the anatomy, physiology, description, or development of the lower cryptogams; the Thoré Prize (200 fr.), for the best work on the cellular cryptogams of Europe; the De la Fons Melicocq Prize (900 fr.), for botanical work done in the north of France. In Anatomy and Zoology, the Grand Prize of the Physical Sciences (3000 fr.), for a biological study of the soft water Nematods; the Savigny Prize (1300 fr.), for the assistance of young travelling zoologists.

In Medicine and Surgery, a Montyon Prize; the Barbier Prize (2000 fr.), for a discovery in surgery, medicine or pharmacy of service in the art of healing; the Breant Prize (100,000 fr.), for a specific cure for Asiatic cholera; the Godard Prize (1000 fr.), for work on the anatomy, physiology and pathology of the genito-urinary organs; the Bellion Prize (1400 fr.); the Mège Prize; the Lallemand Prize (1800 fr.), for the encouragement of work on the nervous system; and the Baron Larrey Prize (1000 fr.), for the best work on military medicine, surgery or hygiene. In Physiology, the Pourat Prize (1400 fr.), for experimental work on the cooling due to muscular contraction; a Montyon Prize (750 fr.), and the Philipeaux Prize (890 fr.), for work in experimental physiology; and a La Caze Prize (10,000 fr.).

Among the general prizes offered are the Arago and Lavoisier Medals, the Montyon Prize for unhealthy trades, the Wilde Prize (4000 fr.), the Cahours Prize (3000 fr.), the Tchihatchef Prize (3000 fr.). for Asiatic exploration, the Petit d'Ormoy Prizes (10,000 fr. each), for work in the mathematical or physical sciences, the Leconte Prize (50,000 fr.), for a new and capital discovery in mathematics, physics, chemistry, natural history or medical science, the Jean Reynaud Prize (10,000 fr.), the Saintour Prize (3000 fr.), the Gegner Prize (3800 fr.), the Trémont Prize (1100 fr.), and the Laplace and Rivot Prizes.

Of these prizes, the Lalande, La Caze, Delesse, Desmazières, Leconte and Tchihatchef are expressly stated as being open without distinction of nationality.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Mr. C. T. R. Wilson, F.R.S., Fellow of Sidney Sussex College, has been appointed University Lecturer in Experimental Physics, in succession to Prof. Wilberforce, now of Liverpool. The appointment of Mr. H. Herbert Smith as Gilbey Lecturer in Agriculture has been confirmed by the Senate.

The following awards in Natural Science have been made at the combined examination for entrance scholarships held by ten of the colleges in December, 1900:—

Clare College.—£60, Leather, Bridlington School; £50, Pears, Clifton College; £40, Byatt, Charterhouse; Johnson Exhibition, Jordan, Bedford School.

Trinity Hall.—£40, Hopkins, St. Paul's, and Potts, Kingswood School.

Trinity College.—£80, Chittock, Harrow; £75, Bulleid, Exeter School; £50, Bray, Harrow; Sizarship, Mottram, St. Olave's; £50, Darwin, Marlborough; £40, Browning, Westminster, Chase, Oundle School, and Hodgson, Bedford rammar School.

Pembroke College.—£40, Straus, Harrow.

Gonville and Caius College.—£60, Whitehead, Battersea Grammar School; £70 (Salomons Engineering Scholarship), Brinton, Cheltenhám College; £30, Coxon, Shrewsbury School.

King's College,—£80, Spens, Rugby.

Jesus College.—£60, Crawford, Nottingham High School.

Christ's College.—£60, Radice, Bedford Grammar School; £40, Bygrave, Giggleswick School; £30, Dobell, Cheltenham College.

St. John's College.—£60, McDonnell, St. Paul's; £40, Jolly, Framlingham School.

Emmanuel College.—£60, Taylor, King Edward's School, Birmingham; £40, Watkins, Shrewsbury School.

THE ninth jubilee of Glasgow University will be celebrated on June 12-14.

FOR many years a large proportion of the national food supply has been dependent on the preservation of meat and fruit in transport and storage by means of artificial cold, so that the subject of refrigeration is one of great and growing importance to the public. Within the last two years a more special interest has been exhibited in this and kindred subjects by the cheaper and more convenient production of liquid air, the proposed applications of it, and the remarkable scientific discoveries to which it has led. Those of the public who wish for authoritative guidance and clear ideas on the whole subject of refrigeration will shortly have an opportunity of obtaining them placed within their reach. The Technical Education Board of the London County Council, acting in conjunction with the Council of University College, London, have arranged for a series of lectures on the artificial production of cold to be delivered in the chemical theatre of the college in Gower Street by Dr. W. Hampson. The lectures will begin on January 18, at 5.30 p.m., and will be illustrated by experiments. Those who wish to attend, or to obtain a syllabus of the lectures, should apply to the secretary of the college. Young engineers, and others who are engaged in practical work in connection with refrigerating machinery or cold storage, and who have not had the advantage of a systematic training in the physical sciences, should find this a useful opportunity of learning to understand better the connection between their work and the scientific principles involved in it.

THE case of Regina *versus* Cockerton is likely to have a profound effect on our national education. As readers of NATURE may remember, a district auditor, dealing with the accounts of the London School Board, disallowed certain sums paid out of the rates for the teaching of science and art in elementary schools according to the rules of the South Kensington "Directory," as distinguished from those contained in the "Code" of the Education Department. These disallowances were brought before Mr. Justice Wills and Mr. Justice Kennedy in the Queen's Bench Division with a view to having them quashed. But the Court has upheld the view taken by the auditor. The London School Board has been non-suited all along the line. To quote Mr. Justice Wills: "It is not within the power of the Board to provide, at the expense of the ratepayers, science and art schools or classes in day schools; . . . science and art classes in evening continuation schools are as much beyond the scope of rate-aided education as in day schools; but that in both such educational work may be carried on by the School Board provided the whole of the funds required for it are furnished from sources other than contributions from the rates." There is little likelihood that the matter will be allowed to rest here; it is bound to go ultimately to the House of Lords. But, whatever may be found to be the present state of the law, one thing the case makes transparently clear, and that is the chaotic condition of English education. As the *Times* said the other day, "by showing up the existing confusion and to some extent aggravating it, the judgment may perhaps hasten some comprehensive scheme for classifying education in a rational way."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, December 13, 1900.—"Additional Notes on Boulders and other Rock Specimens from the Newlands Diamond Mines, Griqualand West." By Prof. T. G. Bonney, F.R.S.

Shortly before the outbreak of the war in South Africa, a parcel of specimens from the Newlands Mine, West Griqualand, was sent

to Mr. C. Trubenbach, managing director in London, who forwarded them to the author for examination. They consisted of (1) boulders, (2) the diamantiferous rock (blue ground), (3) country rock. (1) One angular specimen, a felsite or porphyrite, with fluxion structure, might be only a fragment of a dyke or a flow; the other eight were more or less water-worn. All were holocrystalline igneous rocks, two being saxonites, two varieties of lherzolite, with a few garnets, one an enstatite-eulysite, one an eclogite like those described last year, but without any diamonds, one a hornblendic gabbro, exhibiting an interesting micropegmatitic structure with felspar and pyroxene, and one a diorite. (2) The blue ground presented a general resemblance to that from the De Beers mines—the so-called kimberlite—but its matrix contained a much larger amount of a minute, secondary brown mica. This matrix had been analysed by Mr. C. James at University College, with the result that the CO_2 and H_2O only amounted to 13·55 per cent., the magnesia being 12·14, and the other constituents showing that serpentine could not, at most, form more than about 25 per cent. of the rock. This, then, was yet another proof that the so-called kimberlite could not be an altered peridotite, but was really, as the writer contended, a breccia of rather variable composition. No diamonds were observed this year in the boulders described, but Mr. Trubenbach had obtained another specimen of a pyrope enclosing a small but well-formed diamond. (3) The country-rock. Of this the writer had examined, among others, a variety called "bastard blue" by the miners, which had occurred above the ordinary "blue" and was supposed by them to be related to it. This, however, was not the case. It was a mudstone containing little pebbles of diabase and, more rarely, of a microgranite and a subcrystalline limestone. It was, however, interesting as showing the existence of basic igneous rocks of Triassic or pre-Triassic age. Besides that, and the additional evidence as to the nature of the blue ground, this investigation brought the number of species or strongly-marked varieties of holocrystalline rocks which occur as boulders more or less waterworn up to seven at the very least. The author was of opinion that the most enthusiastic advocate of concretionary action would now be obliged to admit that the specimens, two of which, described in his last paper, had contained diamonds, were rock fragments which had been shaped by the action of water.

Mathematical Society, December 13, 1900.—Dr. Hobson, F.R.S., President, in the chair.—Mr. Basset, F.R.S., spoke on the real points of inflexion of a curve.—Miss Barwell read a paper entitled, "On the conformal representation of polygons on a half plane."—Prof. Elliott, F.R.S., communicated his own paper, "The syzygetic theory of orthogonal Binariants," and gave an account of a paper by Mr. A. L. Dixon entitled "An addition theorem for hyperelliptic functions."—The following papers were communicated by their titles: On some properties of groups of odd order, ii., Prof. Burnside, F.R.S.—On discriminants and envelopes of surfaces, Mr. R. W. Hudson.—Note on the inflexions of curves with double points, Mr. H. W. Richmond.

Zoological Society, December 18, 1900.—Dr. A. Günther, F.R.S., Vice-President, in the chair.—The Secretary exhibited, on behalf of Major A. St. Hill Gibbons, the skull and horns of a white rhinoceros (*Rhinoceros simus?*) from the White Nile, and the mounted heads of two species of Topi antelopes, which had been procured by Major Gibbons during his recent journey through Africa from south to north.—The Secretary also exhibited, on behalf of Sir Harry Johnston, K.C.B., some pieces of skin of an apparently new species of zebra which had been ascertained to inhabit the forest on the banks of the Semleki River near the borders of the Uganda Protectorate.—A communication was read from Capt. Stanley S. Flower, containing an account of the animals he had obtained or observed during Sir William Garstin's expedition to the White Nile. Amongst these were examples of several rare species of antelopes, such as the white-eared kob (*Cobus leucotis*) and Mrs. Gray's kob (*Cobus mariæ*), and numerous specimens of the shoe-bill or whale-headed stork (*Balaeniceps rex*).—A communication was also read from Mr. W. Malcolm Thomson containing an account of a large branchiate polynoid (*Lepidonotus giganteus* Kirk) from New Zealand.—A communication from Mr. H. M. Kyle (of St. Andrews, N.B.), contained a description of a new genus and species of flat-fishes from New Zealand, under the name *Apsetta thompsoni*.—Dr. A. G. Butler contributed a paper on the butterflies lately collected, and presented to the British Museum, by Lord Delamere. The specimens had been obtained chiefly near Mount Kenya, in British East Africa, and had been referred by the author to seventy-nine species, which were enumerated in the paper.—Prof. D'Arcy W. Thompson, C.B., exhibited and described a large specimen of a cuttle-fish (*Ancistroteuthis robusta* Steenstrup) from Unalaska. The generic position of this cuttle-fish had previously been uncertain, owing to the absence of knowledge of the tentacular club. This was now described for the first time, and confirmed Steenstrup's provisional identification.—Mr. F. E. Beddard, F.R.S., described a new species of earthworm under the name of *Amyntas alexandri*. The specimen had been sent to him from Kew Gardens, whither it had been imported from the neighbourhood of Calcutta.

PARIS.

Academy of Sciences, December 24, 1900.—M. Maurice Lévy in the chair.—Formulæ and tables for calculating the times and heights of high and low water, the heights from hour to hour being known, by M. E. Guyou. The heights for three consecutive hours being known, a very simple formula is given for calculating the time of high water.—On the origin of chemical combination and the combination of silver with oxygen, by M. Berthelot. Silver foil, heated with oxygen in sealed tubes at varying temperatures, is slightly attacked, some argentous oxide being formed and the silver becoming different in appearance. This action commences at a temperature of about 200° if the time of heating is very prolonged, and becomes very appreciable at 500°–550° C. If the oxygen is replaced by steam or carbon dioxide the silver is absolutely unchanged.—Silver and carbon monoxide, by M. Berthelot. Silver foil, after four hours heating with dry carbon monoxide at 500°–550°, becomes changed in appearance, and some three to four per cent. of the gas disappears, carbon being deposited and carbon dioxide produced.—Hydrogen and silver, by M. Berthelot. Hydrogen, heated with silver at 550° in a sealed tube, behaves differently from nitrogen, steam or carbon dioxide, as the metal alters considerably in appearance. It is possible that a compound is formed analogous to sodium hydride.—On the theorem of Hugoniot and some analogous theorems, by M. P. Duhem.—The first sign of life, by M. Augustus D. Waller. Following up some researches on the last sign of life, it results that if a *blaze* is the last sign it should also be the first. Some experiments with hens' eggs confirm this view.—On congruences of which the two focal pencils are cyclic, by M. C. Guichard.—The homographic compass, realising by articulations general plane homography, by M. G. Kœnigs.—On Neumann's method of the arithmetical mean, by M. W. Stekloff.—On a series relating to a theory of a linear differential equation of the second order, by M. A. Liapounoff.—On the theta functions of three variables, by M. M. Krause.—The theorem of vortices in thermodynamics, by M. Jougnet.—Permanent modifications of metallic wires and their electrical resistance, by M. H. Chevallier. The same wire is submitted to a series of heatings, which are alternately fixed and oscillating, and the variations of resistance measured. It was found that the permanent variations of resistance are greater when the temperature is oscillating than when it is fixed.—On the electromotive force of magnetisation, by M. René Paillot. It has been shown by M. Hurmuzescu that in a battery formed of two electrodes of iron, one of which is magnetised, the latter becomes positive with respect to the non-magnetised one. These experiments have now been extended to much stronger fields, 30,000 units, and it is found that for a given specimen of iron and acid the electromotive force of magnetisation tends always to a fixed limit.—The luminescence of a rarefied gas round metallic wires communicating with one of the poles of an induction coil, by M. J. Borgmann.—An apparatus allowing several physiological applications of the light produced by an incandescent lamp, by MM. Foveau de Courmelles and G. Trouvé. An application of parabolic mirrors.—On the liquefaction of gaseous mixtures. The isotherms of a mixture, by M. F. Caubet. A discussion of results obtained with mixtures of carbon dioxide and sulphurous acid, and of carbon dioxide with methyl chloride.—A contribution to the study of rarefied gases, by M. Albert Colson.—Influence of pressure on the phenomena of chemical equilibrium, by M. O. Boudouard. A description of some experiments upon the formation of carbon monoxide from carbon dioxide and charcoal.—On the selenides of copper, by M. Fonzes-Diacon. Some new methods of pre-

paring copper selenide, CuSe.—On some chlorobromides of thallium, by M. V. Thomas.—The action of reducing agents upon the two isomeric nitrodimethylacrylic esters, by MM. L. Bouveault and A. Wahl. Of the various substances tried, the only one giving a good yield of the corresponding amido-body was aluminium amalgam, several derivatives of which are described. —On tannase, by M. A. Fernbach. The tannase was prepared by the action of *Aspergillus Niger*, and then rendered sterile by filtration through porcelain.—Tannase, a diastase capable of hydrolysing gallotannic acid, by M. Henri Pottevin. —On the glycolysis of different sugars, by M. P. Portière. Of the sugars examined, the only ones which underwent glycolysis in the presence of the blood of the dog or the rabbit were galactose, lævulose and maltose.—Study of uranium nitrate, by M. Œchsner de Coninck. Densities of aqueous and alcoholic solutions of uranium nitrate, together with some solubilities in some other liquids.—Reaction of *p*-diazobenzene sulphonate of sodium upon the cystinate of iron existing in contaminated waters, by M. H. Causse. A reply to the criticisms of M. Molinié.—On the chemical transformations which take place during the evolution of the bud, by M. G. André. From the point of view of the distribution of the mineral material and organic substances, the evolution of the bud is comparable with the germination of the seed.—On some derivatives of methyl-nonyl-ketone, by M. H. Carette.—On the relations between the chemical constitution of the sexual products and that of solutions capable of determining parthenogenesis, by MM. Yves Delage and Marcel Delage. The theory advanced by Loeb as to the influence of magnesium salts in development requires a difference in the proportion of magnesium salts in the male and female. An experimental study shows that this is not the case, and hence that the proposed theory is inexact.—Germinative cells: male ovules and the cells of Sertoli, by M. Gustave Loisel.—On the signification of the basilar granulations of cilia, by M. P. Vignon.—The physiological relations of intermittent albuminuria, by M. A. Charrin.—Phagocytosis of the Eberth bacillus, by MM. O. F. Mayet and J. Bertrand. The authors have been able to clearly demonstrate the absorption of the Eberth bacillus by the white blood corpuscles.—Cytometric and caryometric researches on the motor nervous cells after the section of their cylindraxis, by M. G. Marinesco. —Remarks on the experiments of Mlle. Barthelet on telegony, by M. Édouard Rogez.—Remarks on the same subject, by M. Giard.—On the parasitism of *Fusarium roseum* and allied species, by M. Louis Mangin.—On the cytology of the Gastromycetes, by M. René Maire.—Variations of structure in a green algæ, *Stichococcus bacillaris*, under the influence of the medium, by MM. L. Matruchot and M. Molliard.—On the development of etiolated plants afterwards turned green by light, by M. H. Ricome.—Effects of annular decortication in some herbaceous plants, by M. Lucien Daniel.—On the age of the granitic *massif* of Cauterets and Néouvielle (High Pyrenees) and of part of the ancient neighbouring formations, by M. A. Bresson.—On the upper Cretacean at Mozambique, by M. Paul Choffat.—The ice caps of the Antarctic regions, by M. Henri Arctowski.—Barometer variations and the synodic revolution, by M. A. Poincaré.—Atmospheric electricity according to observations at the Eiffel Tower and at the central meteorological office, by M. A. B. Chauveau.—On the determination of the density of sea-water, by M. J. Thoulet.

DIARY OF SOCIETIES.

THURSDAY, JANUARY 3.

RÖNTGEN SOCIETY, at 8.—Continental Progress in Practical Radiography and Apparatus: A. W. Isenthal.

FRIDAY, JANUARY 4.

GEOLOGISTS' ASSOCIATION, at 8.—The Geology of Swanage—Chapman's Pool to Punfield Cove (Kimeridge Clay to Upper Greensand): Horace W. Monckton.

MONDAY, JANUARY 7.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—The Early Manufacture of Sulphuric and Nitric Acids: Oscar Guttmann.—Note on the So-called "Heat Test" for Explosives: W. Cullen.

VICTORIA INSTITUTE, at 4.30.—Hornets: Rev. F. A. Walker.

TUESDAY, JANUARY 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Glasgow Bridge: B. H. Blyth. Railway Bridge over the Fitzroy River, at Rockhampton, Queensland: W. J. Doak.—The Niagara Falls and Clifton Steel Arch Bridge: L. L Buck.—Monthly Ballot for new members.

WEDNESDAY, JANUARY 9.

GEOLOGICAL SOCIETY, at 8.—The Geology of South-Central Ceylon: John Parkinson.—Note on the Occurrence of Corundum as a Contact-Mineral at Pont Paul, near Morlaix (Finistère): A. K. Coomára-Swámy.

THURSDAY, JANUARY 10.

MATHEMATICAL SOCIETY, at 5.30.—On the Singularities of Quartic Curves: A. B. Basset, F.R.S.—On Streaming Motions past Cylindrical Boundaries: Prof. Love, F.R.S.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Capacity in Alternate Current Working: W. M. Mordey.——*And, if time permit*: The Use of Aluminium as an Electrical Conductor, with New Observations upon the Durability of Aluminium and other Metals under Atmospheric Exposure: John B. C. Kershaw.

FRIDAY, JANUARY 11.

ROYAL ASTRONOMICAL SOCIETY, at 8.

INSTITUTION OF CIVIL ENGINEERS, at 8.—Geodesy: Wilfrid Airy.

CONTENTS.

THURSDAY, JANUARY 10, 1901.

THE SCIENCE OF ORE DEPOSITS.

Lehre von den Erzlagerstätten. By Dr. R. Beck. 1 Theil. Pp. iv + 384. (Berlin: Borntraeger, 1901.)

IN striking contrast to the almost universal neglect with which the subject of ore deposits is treated in this country is the increasing attention that it is receiving from geologists and mining engineers abroad, and more especially in Germany and in the United States. In the recently published annual general report and statistics of the output of minerals in Great Britain, by Dr. C. Le Neve Foster, attention is called to the fact that our production of all metalliferous minerals, already small, is continually shrinking, and whilst this unpleasant fact may be the cause of the above-noted neglect of the study of ore deposits, it may equally well be an effect thereof, and may present one more example of the way in which we are being left behind by other nations in industrial pursuits, merely because we so uniformly disdain to study their scientific aspects.

The work now under review serves well to emphasise the difference between the treatment of scientific technology in the two countries; it is written by the professor of geology and of the science of mineral deposits at the ancient and famous Royal Mining School of Freiberg. In this country we have no ancient mining schools—perhaps even no mining schools at all, as the Germans understand this term—and not a single professorship devoted to the study of mineral deposits.

This latter subject has nowhere been the subject of more assiduous study than it has at Freiberg, and this fact alone would make the present treatise one of exceptional importance. Its author is, moreover, a recognised authority on the theory of ore deposits, and his work is marked with decided originality in many respects. The only difficulty in forming a fair estimate of it lies in the fact that the volume before us is only half a book, concluding abruptly in the middle of a chapter. It seems that the remainder is not to be published till next year, and as the present part does not include any table of contents it is impossible to say now what the scope of the completed work will be. It is hard to see what good end is to be served by this fragmental system of publication.

The most interesting point about any work on ore deposits is the system of classification and arrangement adopted in it. Dr. Beck commences his work by a division of all deposits into two main groups, (1) Primary, and (2) Secondary, the latter group including the deposits formed by the destruction of pre-existing ones, whether as alluvial deposits or by disintegration *in situ*. It is obvious that such a division is defective in many respects, apart from the fact that the two groups thus formed are of very unequal importance. In the first place it is impossible in many cases to predicate with certainty of an ancient deposit that it was primary in its origin, seeing that all traces of its original genesis may have been lost owing to wide-reaching metamorphism; and, again, there is no real genetic difference between a recent mineral deposit and an ancient one, and it is illogical to base the first great classificatory grouping upon a distinction of such little real importance. Worst of all, the author finds himself unable to maintain his own classificatory system. A striking example of this defect is his inclusion amongst the primary deposits of "bedded gold deposits of Palæozoic and Mesozoic age," the first example of which, given by him, is certainly an alluvial deposit of Cambrian age, whilst all the others were probably also alluvial deposits. Dr. Beck's inclusion of Tertiary and more recent alluvial deposits in his secondary group, whilst all alluvials older than Tertiary are included among primary deposits, is as arbitrary as it is unpractical, and, moreover, is in no way justified by his own definitions.

The group of primary deposits is here further divided into (*a*) *Syngenetic*, or such as were formed contemporaneously with the surrounding rocks, and (*b*) *Epigenetic*, or such as were formed subsequently; the first class is again subdivided into (1) Magmatic segregations, and (2) Stratified ore deposits, and the second class into (1) Fissure veins, and (2) Deposits that are not vein-like; the latter class is again further subdivided, but the deposits included in it are not covered by the present volume, so that their discussion must be deferred. Perhaps the least satisfactory group of the present classification is the first subclass of magmatic segregations, which is intended to cover ore deposits produced by magmatic differentiation from molten eruptive rocks. We doubt whether many geologists would even endorse fully the opening sentence of this section: "The origin of metals is, without doubt, the inaccessible interior of the earth's crust," more especially seeing that the main argument in support of this very dogmatic statement is based upon the high specific gravity of the earth as a whole, compared with that of the rocks composing its surface. This subclass is divided into three sections, namely, segregations of native metals, of oxidised ores and of sulphuretted ores respectively. The first section is especially unfortunate; the first examples quoted, namely, native iron in the island of Disko, nickeliferous iron at Awarua, New Zealand, and platinum in the Urals, are none of them mineral deposits in the sense in which Dr. Beck, quite correctly, defines the word, namely, deposits of mineral of economic importance; further, the last example, namely, the occurrence of native copper in the melaphyres of Lake Superior, is certainly not a case of magmatic segregation, but is a well-marked instance of an epigenetic deposit; and the only other example, that of the occurrence of gold in certain eruptive rocks, is in many cases neither of economic importance nor of indisputably magmatic origin. The next section, that of the oxidised ores, is more satisfactory in many respects, although doubts may well be entertained of the soundness of any system of classification that separates, as widely as Dr. Beck does, the iron ore deposits of Kirunavaara and Luossavaara from those of Gellivaara and Svappavaara, all four of which show very many and very interesting points of similarity. The third section, that of sulphuretted ores, is again open to doubt, and it seems as though more stress had been laid upon the accidental circumstance, whether a given deposit lies wholly within or merely in proximity to an igneous outburst with which it is probably genetically connected,

than upon the real genetic and morphological relations of the deposit. Hence it is that Dr. Beck places the pyritic deposits of Rio Tinto, Mount Lyell, &c., in quite a different group from those of Sudbury, although most authorities prefer to group them together. Moreover, it is only in very few of the examples cited under this head that the magmatic origin of the deposit can be said to be in any degree probable.

The class of the stratified ore deposits is better defined, although it would have been preferable to have either excluded altogether deposits that consist of ores disseminated through an otherwise barren bed, or else to have included all forms of this mode of occurrence; the attempt to class impregnations amongst the epigenetic deposits, and to include in the present class only such disseminations as were formed contemporaneously with the bed in which they occur, is necessarily unsatisfactory, for there are very few instances in which the true mode of origin of such deposit has been proved beyond the possibility of dissent. Another source of weakness in this classification is the inclusion here of typically lenticular deposits, whenever the lens lies parallel to the stratification. Here again a relatively accidental character has been emphasised whilst the real geological relations of the deposit have been lost sight of.

Dr. Beck is perhaps at his best in his classification of veins, although the method here adopted is purely empirical. Such important geological relations as those of the vein to the country rock are utterly disregarded, contact veins are not distinguished from true fissure veins, &c., whilst the classification relies entirely upon the mineralogical character of the vein filling. This is the old Freiberg classification, revised and extended, and though it is less satisfactory when applied to the world as a whole than it was when restricted to the Freiberg district, it is nevertheless interesting, and, to a certain degree, even useful. By far the worst portion, and the only one that is wholly unsatisfactory, is the attempt to classify the gold-bearing veins, the distinctions here drawn being far too artificial, and the lines of demarcation too imaginary.

It may be noted, by the way, that the well-known Sheba deposit is here classed as a vein, whilst the bulk of what is known about it tends to show that it is certainly a bed. It is also doubtful whether the majority of the cinnabar deposits are really veins, as they are here designated.

In pointing out that many and grave faults can be found with Dr. Beck's classification of ore deposits, nothing more is intended to be conveyed than that Dr. Beck has not succeeded where every one else has failed. It may be doubted whether any one has yet evolved a classification of ore deposits that satisfied anybody—even its author; the inherent difficulties of the subject are so great and so manifold that a satisfactory solution of the problem may, in the present state of the science, fairly be declared to be impossible. Classification apart, Dr. Beck's work forms a contribution of the utmost value to the study of ore deposits; his descriptions are concise and clear, and his illustrations are well selected, especially as regards German, Austrian and Scandinavian deposits. The section on faults is eminently satisfactory, and indeed it would be hard to point to any work in which this complicated portion of the subject has received better treatment. It is difficult to pass judgment on half a book, but it may fairly be said that if the remainder of the work is only equal to the first half, it will constitute one of the best works available on the subject of ore deposits, provided that it is furnished with thoroughly complete indexes, and not with the apology for an index that usually does duty in German works. As the ore deposits described are arranged in accordance with the author's own system of classification, a complete alphabetical subject-index, together with a complete alphabetical index of geographical names, are needed to make Dr. Beck's work the highly useful book of reference that its other merits entitle it to become.

H. LOUIS.

THE THEORY OF "SCREWS."

A Treatise on the Theory of Screws. By Sir Robert Stawell Ball, LL.D., F.R.S. Pp. xix + 544. (Cambridge University Press, 1900.)

SIR ROBERT BALL'S "Theory of Screws" is one of the most notable modern extensions of theoretical dynamics. It is based on Poinsot's discovery that every set of forces, regarded as acting on a rigid body, is reducible to a force along one definite line and a couple round the line; combined with Chasles's discovery that every instantaneous motion of a rigid body is reducible to rotation round one definite line and translation along it—in other words to a screwing motion. The modes of reduction in the two cases are strictly analogous; a force along a line being the analogue of a rotation round the line, and translation in any direction being the analogue of a couple whose axis has this direction.

The theory of screws treats of these two subjects in conjunction. The definite line along which the force acts, or round which the body rotates, is regarded as the *axis* of a *screw*, and the ratio of the couple to the force in the one case, or of the translation to the rotation in the other, is called the *pitch* of the screw. The sign of the pitch indicates whether the screw is right-handed or left-handed, and is not altered by reversing the screw end for end.

It would be convenient to have some general name for anything which follows the laws of combination employed in these reductions. Clifford called it a *motor*. It might well be called a *screw-actor*. The resultant of two screw-actors may be called their *sum*.

When the screw-actor is a set of forces, Sir R. Ball calls it a *wrench*—a name which is not suggestive of a statical concept, but rather of force combined with motion. The name *forcive* seems more appropriate.

When the actor is a screw motion, Sir R. Ball calls it a *twist*, and the name *twist-velocity* is given to a screw-velocity. The twists considered in the theory of screws are, in general, supposed to be so small as to admit of simple superposition, quantities of the second order being negligible.

Five numbers are required for specifying a screw. Two will give the direction of the axis, two the intersection of the axis with a fixed plane, and one the pitch. From another point of view a screw is defined by the five ratios of the six components of a screw-actor.

The theory of screws lends itself with special readiness to the discussion of the movements of a body with a given number of degrees of freedom. A body with one degree

of freedom can only move on one definite screw. A body with two degrees of freedom can take two independent screw motions combined in any ratio. This gives an infinite number of resultant screws, all lying in one ruled surface (called a *cylindroid*) and having pitches distributed according to a simple law. All cylindroids have the same shape, and the linear dimensions of a cylindroid are proportional to the difference between the greatest and least pitch that can be found among its screws. A body with n degrees of freedom has n independent screw motions, n being not greater than 6.

Any screw system which specifies the freedom of a body serves equally well for specifying aggregates of screw-actors of the forcive kind. For instance, if any multiple (integral or fractional) of a forcive on a screw A is compounded (additively or subtractively) with a forcive on a screw B, the resulting forcive will be on one of the screws of the cylindroid to which A and B belong.

A body limited to motion on one definite screw can move in either of two opposite directions, and when acted upon by a forcive will move in the direction for which the work done by the forcive is positive. When the forcive-screw is so related to the motion-screw that the work-rate for a small motion is zero, the body will be in equilibrium, the forcive being equilibrated by the reaction of the constraints. The two screws in this case are said to be *reciprocal*. The condition of reciprocity, when expressed in terms of the rectangular components X Y Z of force, $u\ v\ w$ of translation, L M N of couple, and $p\ q\ r$ of rotation, is

$$Xu+Yv+Zw+Lp+Mq+Nr=0;$$

and this will not be altered by interchanging the force X with the rotation p, the couple L with the translation u, and so on. Hence it is immaterial which of the two screws we assign to the forcive and which to the motion.

One degree of constraint subjects the 6 components, $u\ v\ w\ p\ q\ r$, of an instantaneous motion to one linear relation. It can accordingly be expressed by assigning proper values to the coefficients X Y Z L M N in the above equation of condition. One degree of constraint, therefore, limits the motion of a body to those screws which are reciprocal to one definite screw. Hence it can be deduced that two degrees of constraint limit the motion to screws reciprocal to all the screws of one definite cylindroid.

The system of screws on which a body can move which has n degrees of freedom or $6-n$ degrees of constraint being called an *n system*, it can be shown that every n system is reciprocal to a definite $6-n$ system. Each of these two systems is sufficient to define the other.

In a 5 system the axes of the screws include every line in space, each fitted with its proper pitch, and at every point there are a whole plane of screws of any assigned pitch.

Three or more screws are said to be independent when it is not possible to take screw-actors upon them whose sum is zero. Seven screws cannot be independent. If any 6 independent screws are taken, they will suffice for the specification of any 7th screw by 6 numerical coefficients, called *screw-coordinates*, an actor on the 7th screw being always a sum of multiples (generally fractional) of actors on the 6 screws of reference. It is possible, and usually preferable, to select screws of reference such that each is reciprocal to all the rest.

If a body is only free to move on a single screw, a forcive applied to it can be resolved into two forcives, one of which is reciprocal to the screw in question. This component can be ignored, as it does not influence the motion, which will accordingly be the same as if the other screw acted alone. If a body has n degrees of freedom, a forcive applied to it can be resolved into 6 mutually reciprocal forcives of which $6-n$ are without influence on the motion, and the other n may be regarded as acting alone.

The initial motion of a body produced by an impulsive forcive is, in general, on a different screw from the forcive; but in certain cases they are on the same screw. (This means that they have the same axis, and the work in translation is equal to the work in rotation). The screw, common to both, is then called a *principal screw of inertia*. There are, in general, 6 such screws for a perfectly free body, and n for a body with n degrees of freedom.

Again, for a body in stable equilibrium under forces which have a potential, there are certain screws (generally equal in number to the degrees of freedom) such that if the body be slightly displaced along one of these screws, and then left to itself either at rest or with a velocity on the same screw, it will oscillate on this screw. The screws thus defined are called *harmonic*, and are the proper screws to select for specifying small oscillations.

Besides physical deductions, of which the foregoing are specimens, the treatise contains numerous geometrical investigations, and an extension of the theory to non-Euclidian space.

At the end of the volume an interesting summary is given of the literature of the subject. It appears that Hamilton, in one of his papers on systems of rays, and Plücker, in his *New Geometry of Space*, anticipated Sir R. Ball's discovery of the cylindroid so far as regards its geometrical form without reference to pitch; and several theorems respecting systems of lines had been discovered which are particular cases of the general theory of screws.

An amusing and instructive "Dynamical Parable," which formed Sir R. Ball's Presidential Address to Section A at the 1887 meeting of the British Association, is given as an Appendix.

I wish to point out an erroneous statement with regard to finite displacements which occurs in all our works of highest authority on the motion of a rigid body. It is to be found in *Routh*, in *Thomson and Tait*, in *Williamson and Tarleton*, and in the introduction to Sir R. Ball's *Treatise*. The erroneous statement, in its plainest shape, is "The same displacement cannot be constructed on two different screws."

To see that this is wrong, consider the effect of giving a nut $9\frac{1}{4}$ turns on an ordinary iron screw. The same final position could obviously be attained by employing a screw of longer pitch and taking fewer turns, say $8\frac{1}{4}$ or $1\frac{1}{4}$ or $\frac{1}{4}$, and could also be attained by taking $\frac{3}{4}$ or $1\frac{3}{4}$ or $8\frac{3}{4}$ turns on a left-handed screw. The correct statement is that the axis and translation are unique, but that the rotation has any one of an indefinite number of values differing each from the next by 2π, some of them being

positive (right-handed) and some negative (left-handed). If l is the translation, and p_0 one value of the pitch p, the general value of p is given by

$$\frac{1}{p}=\frac{1}{p_0}\pm\frac{2n\pi}{l}.$$

J. D. EVERETT.

CULTIVATION AND MANUFACTURE OF TOBACCO.

Le Tabac Culture et Industrie. By E. Bouant. Pp. xii+347. (Encyclopédie Industrielle, Paris: J. B. Baillière et fils, 1901.)

THE object of this work, as stated by the author in the preface, is to describe in popular scientific language the long series of operations necessary to transform a tiny seed into a good cigar or a pinch of scented snuff.

In a short introduction the author gives a *résumé* of the best ascertained facts concerning the origin of tobacco, its introduction into Europe, the prohibitions intended to hinder its use, and the change of tactics which have resulted in making the smoker contribute his quota to the public revenue.

Of the three parts into which the book is divided, the first two deal with the cultivation and manufacture of tobacco, and in the third part the economic, fiscal and hygienic aspects of tobacco are discussed.

In France the State controls the cultivation, and has the monopoly of the manufacture of tobacco; the author restricts his treatment of the subject almost entirely to a description of the methods of culture and manufacture followed in France.

Part i. commences with the botany of the principal species of Nicotiana and with a short account of the chemistry of tobacco. According to the analyses given on p. 24, tobacco ash contains a large proportion of salts of sodium (16 per cent. in the ash from the leaves of Havana tobacco). This is at variance with the general experience, for it is a remarkable and well-established fact that tobacco contains very little soda in any form.

The subject of culture is dealt with very fully, and a large amount of information is given concerning the choice of the most favourable soils and manures, the rotation of crops, sowing and transplanting, the various field operations during growth and ripening, and the final operations of harvesting, curing and packing.

In view of the experimental cultivation of tobacco which has been carried on in Ireland during the past season, it is interesting to note that the experience gained in France shows that Europe will never be able to dispense with American tobacco, as, with rare exceptions, European varieties are inferior in aroma and combustibility to those of American origin.

The manufacturing methods described in the second part are those employed in the great State tobacco factories of France. The methods of manufacturing cut and roll tobacco and snuff differ materially from those followed by British manufacturers, the result, no doubt, of the different fiscal regulations in the respective countries. The methods employed for making cigars and cigarettes, on the whole, are the same in both countries.

The book is well illustrated and, with the exception of a few photographic reproductions which leave much room for improvement, the illustrative figures are good and clear; typographical errors are not numerous. Altogether it is a very readable work, and, in addition to being interesting to the general reader, it should be of some service to those engaged in the cultivation and manufacture of "our holy herb Nicotian." J. W.

OUR BOOK SHELF.

Briefwechsel zwischen Franz Unger und Stephan Endlicher. Herausgegeben und Erlaütert von G. Haberlandt. Pp. v. + 184. (Berlin: Borntraeger, 1899.)

AFTER the death of Unger's surviving son and daughter, a large portion of his correspondence was presented to the Botanical Institute of the University of Graz. From amongst these remains Prof. Haberlandt gives to the world the almost complete series of letters which passed between Unger and Endlicher from 1829 to 1847. There are 139 letters in all, of which about two-thirds are by Unger. Though the correspondence is, in large part, concerned with their own botanical labours, all the more important contemporary contributions to Botany are discussed between the friends. At the date of the opening of this correspondence, neither of the writers held an independent botanical post. Unger, who had deserted the law and qualified in medicine, in 1830 became a medical officer at Kitzbühel, in the northern Tyrol. Here, during his five years' sojourn, he collected the material for and wrote his now classic "Einfluss des Bodens auf die Vertheilung der Gewächse." This was the first attempt at a physiological flora, and Unger was justly proud of his achievement. This and other work paved the way to the professorship at Graz, to which he was appointed in the autumn of 1835, and which he held till Endlicher's death. Endlicher, the author of the well-known "Genera Plantarum," was made keeper of the botanical department in the Hof Museum, at Vienna, within a few months of Unger's appointment to Graz. Many common undertakings were mooted between the friends, and the most notable of those which reached accomplishment was their joint "Lehrbuch der allgemeinen Botanik," published in 1843. Its inception and progress are very fully set forth in the letters, and this portion of the correspondence will be read with interest as effectively contrasting the character and temperament of these two men. That Schleiden should have chosen the same time to bring out his remarkable "Grundzüge der wissenschaftlichen Botanik" was an event which could not fail to impress the joint authors. Unger, with characteristic outspokenness, writes :—"What do I think about Schleiden? He is an excellent fellow, though I don't agree with him entirely. We have wanted a man like this for a long time. It is by him—not by us—that a new epoch is created in our science." Another part of the correspondence, that relating to Unger's discovery of the ciliated zoospores of *Vaucheria*, is also full of interest. The headstrong and enthusiastic Unger insists on announcing his discovery in the form of a series of popular letters under the title "The Plant at the Moment of becoming an Animal," with an absurd quotation from Oken (the nature-philosopher) as motto. This intention draws from Endlicher one of the best letters in the book (No. 100); but it is quite lost upon Unger.

The correspondence is preceded by an able appreciation of the two botanists by Prof. Haberlandt, the present occupant of Unger's chair at Graz; whilst, by way of conclusion, there is printed a series of documents which tends to show that Endlicher died a natural death and did not commit suicide, as has been generally believed.

The British Journal Photographic Almanac, 1901. Edited by Thomas Bedding. Pp. 1552. (London: Henry Greenwood and Co., 1900).

THE fourth annual issue of this photographic almanac seems to be as popular as ever, judging by the great amount of matter contained in the present volume There are no less than 1552 pages, about 500 of which form the text. The arrangement of the book is the same as that adopted last year. There are over eighty articles on practical subjects, written by photographers, and these contain many useful hints which should be of service to those who utilise the experience of others. The "epitome of progress of the year," compiled by the editor, is very interesting reading, references to the most important advances being liberally made. "Recent novelties in apparatus" and "practical notes and suggestions of the year" also form no inconsiderable portion of the volume. The great collection of formulæ, tables, measures, photographic societies of the United Kingdom, &c., makes the volume a necessary accessory to any photographic studio.

Among the mass of material will be found some excellent illustrations, the frontispiece being a bromide print by Messrs. Morgan and Kidd. Not the least useful portion of this volume is the great collection of advertisements of most of the photographic manufacturers and dealers. The volume is quite up to, if it does not exceed, the standard of last year, and should be in the possession of all photographers. The price of one shilling brings it within the reach of all.

The Lead Storage Battery. By Desmond G. Fitz-Gerald. Pp. xi + 383. (London: Biggs and Co., no date.)

IN spite of the great industrial application of the accumulator, the theory of its working is in a very unsatisfactory state; and, moreover, those who desire to obtain information on the subject are obliged to seek for it in the publications of scientific institutions. Mr. Fitz-Gerald's book is a very useful summary of the leading facts and theories of the subject. Whilst fulfilling in some respects the objects of a text-book, it is much more than a text-book. Mr. Fitz-Gerald is able to speak with authority on both the chemical and electrical aspects of the storage cell, and his criticisms of existing types and suggestions of possible improvements will be found in many cases very valuable indications of what are likely to prove profitable lines of research. At the same time the book should be in the hands of any one who has to deal with accumulators, especially electrical engineers, who too often are quite ignorant of the chemistry of the subject. Besides discussing the various theories of the accumulator, the author gives an interesting account of its development, and descriptions, which are, we are inclined to think, too brief, of the different types of cell in use.

Mr. Fitz-Gerald apologises in the preface to the book for its possessing the defects of a compilation from notes made from time to time. It would have been better if, instead of making this apology, the author had removed the defects and had made the book a more consecutive work. It is difficult to make out to whom the book is intended to appeal, as in some instances elaborate calculations are entered into on points so elementary as to be quite childish, whilst in others a knowledge of chemistry is assumed which we doubt if the average electro-chemist possesses and feel sure is not possessed by the majority of electricians. In addition, the parts devoted to the history and theory of the subject respectively are intermixed without any apparent reason, and lose greatly in continuity and clearness in consequence. These defects are the more to be deplored as it is to be feared that they will discourage many from reading the book.

The Elements of Inorganic Chemistry. For Use in Schools and Colleges. By W. A. Shenstone, F.R.S. Pp. xii + 506. (London: Edward Arnold, 1900.)

THE object of the author of this elementary text-book is clearly stated in his preface. He says:—

"I have endeavoured to provide a book which begins with a course of experimental work for quite young students, and develops at the later stages into a text-book suitable for those who are older—that is, into a text-book containing fewer facts than those written solely for senior students, and in which the powers of young workers are more carefully kept in view in the earlier and middle parts than is necessary in the case of books written for students of a different type."

The book is divided into five parts. Part i. is chiefly taken up with the study of water and air, as exemplifying some of the principal types of chemical action and physical properties; Part ii. treats of the laws of combination and the atomic theory; Part iii. of the non-metals and their principal compounds; Part iv. of chemical affinity, heat changes, electrolysis, spectrum analysis and crystallography; Part v. of the metals and their chief compounds.

Directions are given for the performance of several hundreds of experiments, most of which can be done by the student himself. These directions, like the diagrams of apparatus which illustrate them, are very simple and clear.

The book seems extremely well adapted to the wants of the class of students the author has in view. Any youth of ordinary intelligence who works through the volume under the supervision of a competent demonstrator will acquire, not only an adequate knowledge of the facts of chemistry, but also sufficient theory to enable him to range and systematise these facts and to understand their general bearing.

The Thompson-Yates Laboratories Report. Edited by Profs. R. Boyce and C. S. Sherrington. Vol. i., Reprints, 1898–99; Vol. ii., Reprints and Reports, 1898–99; Vol. iii., Part 1, 1900. (Liverpool: University Press.)

THESE three handsome volumes testify to the energy and vitality of the Liverpool school. After a preliminary account of the laboratories founded by the munificence of the Rev. Thompson-Yates, vol. i. is devoted to neurology, and contains papers and reprints by Profs. Sherrington and Boyce, and Drs. Warrington, Laslett and Grünbaum, of which the one by the first-named author, upon the peripheral distribution of some spinal nerves, forms the *pièce de resistance*, occupying more than half the book. There are also interesting papers upon the changes found in lead paralysis and upon the muscle-spindles in pseudo-hypertrophic paralysis. In the latter, Grünbaum considers that his observations support the theory that this disease is a primary one of the muscles.

The first half of vol. ii. contains papers and reprints in bacteriology, hygiene and morbid anatomy, of which Dr. Balfour Stewart contributes three on plague—its diagnosis, and on the active constituents of Haffkine's prophylactic, Dr. Annett an interesting *résumé* of the tubercle-like bacilli in butter, and the same author an experimental inquiry on the use of boric acid and formaline as milk preservatives, in which he shows that kittens fed on milk containing these two substances are injuriously affected. The account of the morbid anatomy and pathology of a case of myelopathic albumosuria, by Drs. Bradshaw and Warrington, is a valuable contribution to our knowledge of this very rare disease, which was first described by Bence Jones, and of which only seven other cases have been recorded. Next follow the reports of the various departments and, as a supplement, Profs. Boyce and Herdman's report on oysters and disease, and the report of the Malarial Expedition to West Africa.

Vol. iii. is similarly mainly bacteriological. Balfour Stewart shows the wide distribution of the *Bacillus enteritidis sporogenes* of Klein, MacConkey contributes a paper on the differentiation and isolation of the *Bacillus coli* and *Bacillus typhosus* from mixtures by means of media containing bile salts.

The printing, illustrations and general "get-up" of the volumes are excellent. There is, perhaps, a tendency to needless detail in some places, as, for example, in the list of milk samples, but many of the papers are contributions of real scientific value.

Einführung in die Stöchiometrie. Von Joachim Biehringer. Pp. xviii + 498. (Brunswick: F. Vieweg und Sohn, 1900.)

THIS book, which differs greatly from the ordinary text-books of chemistry, has for sub-title "A study of the quantitative composition of substances and the properties connected therewith." So far as subject-matter is concerned, it covers much the same ground as Part i. of Ostwald's *Allgemeine Chemie*, the general arrangement evidently being inspired by that work. The treatment, however, is radically different, theoretical matters, although adequately outlined, being made subservient to their practical applications, which are illustrated by a wealth of numerical examples. The arithmetical exercises are, in fact, the chief feature of the book. There are altogether three hundred of them, each of which is provided with a fully-worked solution, the method of calculation being carefully explained. The problems are well-selected, unpedantic, and of real value in their application to laboratory or technical work. Some are, perhaps, a little far-fetched, but even these are instructive, and almost always possess some human interest. For example: "It is desired to convert into sparkling wine 1000 litres of new wine containing 10 per cent. by volume of alcohol and 0·5 per cent. of unfermented sugar. How much cane-sugar must be added in order that after fermentation the wine may have a pressure of 5 atmospheres, the temperature of the cellar being 12°?" The student will be especially grateful for the numerous examples of the calculation of molecular weights, and of the results of analysis, both gravimetric and volumetric. Altogether no better guide could be desired to chemical and elementary physico-chemical calculations.

Travail des Metaux dérivés du Fer. Par L. Gages, Capitaine d'Artillerie. "Encyclopédie Scientifique des Aide-Memoire." Pp. 202; 40 illustrations. (Paris: Gauthier-Villars, 1900.) Price 2 fr. 50 centimes.

THIS new member of the excellent *aide-memoire* series worthily upholds the reputation built up by its predecessors. It gives in clear, terse language a short summary of the mechanical and thermal treatment to which steel is subjected to prepare it for use in the industries, and the greater part of the remainder of the book is given up to considerations of the theory of hardening and tempering. The solution theory of the constitution of steel is so firmly established in France that it is now taken as an authoritative explanation of the facts; but some of the thermal and micrographic evidence is given, on which the theory is based. In dealing with "steels" which owe their distinctive properties to the admixture with iron of elements other than carbon, Captain Gages makes a new departure in classifying them in accordance with a law enunciated by Sir William Roberts-Austen, which sets forth the fact that elements having a lower atomic volume than iron tend to harden steel, and those with a higher atomic volume to soften it and make it malleable. This classification of a large class of materials which are comparatively new to engineers seems useful and businesslike, and, indeed, Captain Gages, by bringing into a brief and readable form the results of the labours of Osmond, Werth and many others, has done much to popularise the whole subject.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Stability of a Swarm of Meteorites.

REFERRING to my paper in NATURE of October 11, "On the Stability of a Swarm of Meteorites, &c.," Mr. R. B. Hayward, F.R.S., has called my attention to the fact that the supposition, made near the foot of the first column, that

$$\xi = a\cos\omega t,\ \eta = b\sin\omega t,$$

in other words that the relative orbit of the particle under consideration is an ellipse of semi-axes a, b, involves an eccentricity,

$$\sqrt{1-b^2/a^2},$$

for that ellipse of amount

$$n\sqrt{3/(\mu-\omega^2)} = \sqrt{6n/(\sqrt{n^2+16\mu}-n)},$$

so that in strictness the relative orbit cannot be a circle unless $n=0$.

This point ought, perhaps, to have been brought out in my paper as illustrating the rudeness of the approximation of the shape of the swarm to a sphere in any actual case, a matter which I touched on in speaking of the inutility of further refinements, such as the effect of the ellipticity of the swarm's orbit round the sun. However, for any probable swarm in the solar system, n^2/μ must be a very small fraction, and so ω^2 may be very nearly equal to μ (if the centre of the swarm is fixed, $\mu=\omega^2$), while b/a is nearly unity.

Mr. Hayward suggests that the same difficulty may have been felt by others, and that therefore the above explanation may be desirable. ANDREW GRAY.

The University, Glasgow, December 29, 1900.

An Artificial Representation of a Total Solar Eclipse.

IN preparing for polarisation experiments on the solar corona, it is extremely desirable to have an artificial corona as nearly as possible resembling the reality for preliminary work. The only device of the kind that has been used to my knowledge was the arrangement described by Wright in his eclipse report, consisting of a cardboard funnel, lined with black cloth, with a light at the back. This gives a ring-shaped illuminated area radially polarised. It is believed that the contrivance about to be described will be found far better adapted to work of this sort, for the artificial corona in this case resembles the real so closely as to startle one who has actually witnessed a total solar eclipse. The polarisation is radial, and is produced in the same way as in the sun's surroundings, and the misty gradations of brilliancy are present as well. So perfect was the representation that I added several features of purely æsthetic nature to heighten the effect, and finally succeeded in getting a reproduction of a solar eclipse which could hardly be distinguished from the reality, except that the polar streamers are straight, as drawn by Trouvelot, instead of being curved, as all the recent photographs show them. The curious greenish-blue colour of the sky, and the peculiar pearly lustre and misty appearance are faithfully reproduced. For lecture purposes an artificial eclipse of this sort would be admirably adapted, and I know of no other way in which an audience could be given so vivid an idea of the beauty of the phenomenon. Drawings and photographs are wholly inadequate in giving any notion of the actual appearance of the sun's surroundings, and I feel sure that any one will feel amply repaid for the small amount of trouble necessary in fitting up the arrangement which I shall describe.

A rectangular glass tank about a foot square on the front and five or six inches wide, and a six candle-power incandescent lamp are all that are necessary. The dimensions of the tank are not of much importance, a small aquarium being admirably adapted to the purpose. The tank should be nearly filled with clean water, and a spoonful or two of an alcoholic solution of mastic added. The mastic is at once thrown down as an exceedingly fine precipitate, giving the water a milky appearance. The wires leading to the lamp should be passed through a short glass tube, and the lamp fastened to the end of the tube with sealing wax, taking care to make a tight joint to prevent

the water from entering the tube (Fig. 1). Five or six strips of tinfoil are now fastened with shellac along the sides of the lamp, leaving a space of from ½ to 1 mm. between them. The strips should be of about the same width as the clear spaces. They

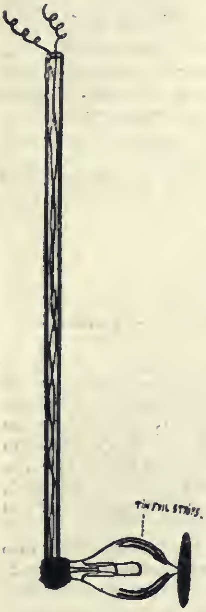

FIG. 1.

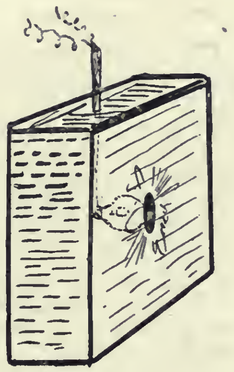

FIG. 2.

are to be mounted in two groups on opposite sides of the lamp, and the rays passing between them produce the polar streamers. The proper number, width and distribution of the strips

FIG. 3.

necessary to produce the most realistic effect can be easily determined by experiment. A circular disc of metal a trifle larger than the lamp should be fastened to the tip of the lamp with sealing-wax, or any soft, water-resisting cement; this cuts off the direct light of the lamp and represents the dark disc of the moon. The whole is to be immersed in the tank, with the lamp in a horizontal position and the metal disc close against the front glass plate (Fig. 2). It is a good plan to have a rheostat in circuit with the lamp to regulate the intensity of the illumination. On turning on the current and seating ourselves in front of the tank, we shall see a most beautiful corona, caused by the scattering of the light of the lamp by the small particles of mastic suspended in the water. If we look at it through a Nicol prism we shall find that it is radially polarised, a dark area appearing on each side of the lamp, which turns as we turn the Nicol. The illumination is not uniform around the lamp, owing to unsymmetrical distribution of the candle-power, and this heightens the effect. If the polar streamers are found to be too sharply defined or too wide, the defect can be easily remedied by altering the tinfoil strips. The eclipse is not yet perfect, however, the illumination of the sky background being too white and too brilliant in comparison. By adding a solution of some bluish-green aniline dye (I used malachite-green), the sky can be given its weird colour and the corona brought out much more distinctly. If the proper amount of the dye be added, the sky can be strongly coloured without apparently changing the colour of the corona in the slightest degree, a rather surprising circumstance, since both are produced by the same means.

We should have now a most beautiful and perfect reproduction of the wonderful atmosphere around the sun, a corona of pure golden white light, with pearly lustre and exquisite texture, the misty streamers stretching out until lost on the bluish-green background of the sky. The rifts or darker areas due to the unequal illumination are present as well as the polar streamers. The effect is heightened if the eyes are partially closed.

A photograph of one of these artificial eclipses is reproduced in Fig. 3. Much of the fine detail present in the negative is lost in the print, and still more will doubtless go in the process of reproduction. No especial pains were taken to get the polar streamers just right.

Sexual Dimorphism.

I CRAVE your leave to reply to one part of the careful and considerate criticism with which Prof. Meldola has honoured my book on "Sexual Dimorphism." He declares his inability to see any force in one of the crucial arguments of my theory, namely, that concerning unisexual inheritance, or, in Darwin's phraseology, heredity as limited by sex. He asks, Why should characters mechanically impressed upon the male during a particular period of his life be hereditary, and characters arising by spontaneous variation at that period not be hereditary? But this is not the question we have to consider. The question discussed in my argument is, Why should characters arising by spontaneous variation at any period of life in one sex be inherited by offspring of the same sex, and not by offspring of the opposite sex?

Prof. Meldola maintains that *on either hypothesis* all characters must originate in an individual which must be either male or female, and asks why there should ever be any blending of characters at all. He appears, therefore, to suppose that all spontaneous variations are inherited only by offspring of the same sex as the parents in which they occurred. It is well known that this is not the case. Many instances are on record in which additional fingers have occurred in a man, and have been inherited by both male and female descendants. I have myself much experience in breeding mice, and in them, although the colours of the parents do not blend perfectly or always in the offspring, yet the colour of the male parent is not more often inherited by male progeny than by female. On the other hand, blending often occurs, and if a male pouter pigeon is matched with a female fantail, the male progeny are not perfect pouters, nor the female perfect fantails.

Darwin has discussed the question in a well-known passage ("Descent of Man," 2nd edit. p. 231): "If a breeder observed that some of his pigeons varied into pale blue, could he, by long continued selection, make a breed in which the males alone should be of this tint, whilst the females remained unchanged? I will here only say that this, though perhaps not impossible, would be extremely difficult; for the natural result of breeding from the pale blue males would be to change the whole stock of both sexes to this tint. If, however, variations of the desired

tint appeared, which were from the first limited in their development to the male sex, there would not be the least difficulty in making a breed with the two sexes of a different colour, as, indeed, has been effected with a Belgian breed, in which the males alone are streaked with black."

The necessary assumption of the theory of sexual selection therefore is, not that spontaneous variations are always inherited unisexually, but that congenital variations occur and have occurred in certain species which from the first were limited in development to one sex. The selection or preservation of such variations does not explain their unisexual or other limitations. It might be suggested or maintained that spontaneous hereditary variations, limited to one sex, to one period of life, or to one season of the year, are liable to occur and have occurred in all species, but have been only selected and preserved in some. But I do not know that this is maintained by selectionists, and at any rate I know of no evidence to support such a contention.

The questions I have considered are, Why have such hereditary variations occurred in some species and not in others? Why are they so closely correlated with the functional activity of the testes, actually failing to develop normally in castrated animals? Why do they always, so far as we know, correspond to the special stimulations involved in the behaviour of the animals under sexual excitement?

Prof. Meldola asks, Why should my view be supposed to account for the limitation of the male characters to the male and the Darwinian view to fail? Surely it is obvious that Darwin's theory merely assumes that variations have occurred which from the first were limited in development as the characters are, while my theory is that they were so limited in development because they were due to stimulations similarly limited.

When Prof. Meldola suggests that the female has had any tendency to inherit the male characters eliminated by natural selection, he seems to me to be repeating an empty formula. There is no ground for supposing that any selection could eliminate such a tendency, and, further, it is an established fact that the tendency has not been eliminated; the female inherits the characters potentially, but in her they usually remain suppressed and latent to appear in actual development under certain conditions. J. T. CUNNINGHAM.

Penzance, December 29, 1900.

MR. CUNNINGHAM'S reply does not appear to me to shed any new light upon the subject of unisexual inheritance, and I can only adhere to the statement expressed in my review. Why he credits me with the supposition "that all spontaneous variations are inherited only by offspring of the same sex as the parents in which they occurred" is beyond my comprehension. There is nothing in my criticism of his views which warrants this, and I need hardly add that the facts which prove such a supposition to be erroneous are quite as familiar to me as they are to Mr. Cunningham. The real point at issue is a comparatively simple one. The author of the book insists that the theory of sexual selection fails to account for unisexual inheritance, and that his theory does account for this phenomenon. Again, it may be asked, why? The answer given above is simply a repetition of his opinion, as already published—the characters are so limited "*because they were due to stimulations similarly limited.*" That is to say, that in every case where the male possesses distinctive secondary sexual characters, these have been produced by direct stimulations acting on the male only, and are, therefore, limited by heredity to the male. Now Mr. Cunningham has just pointed out that transference of male characters to the female does take place, that blending of characters may, and does, occur, and that male characters may, under certain circumstances, appear in the female—a series of facts which we have all been familiar with ever since we became students of Darwin's writings. These facts are absolutely inexplicable on the "direct stimulation" theory. If the stimulations which produced a male character necessitate the restriction of that character to the male, then the only way of escaping from the dilemma in which the author has placed himself is to make one of two additional assumptions:—(1) The characters so blending are not secondary sexual characters, which would be simply resolving the question at issue into a verbal juggle; or (2) that in all cases where there is blending or transference, the same "stimulations" have acted upon both sexes. This last assumption is, however, opposed to the entire spirit of Mr. Cunningham's book, the whole burden of which is that there has been *dissimilarity* of "stimulation" between the sexes.

I should like to add, in concluding, that my own opinion as to the value of Mr. Cunningham's book is in no way shaken through my inability to accept his amended Lamarckism. Out of gratitude for the body of facts which he has collected, I will even go so far as to meet that much-hackneyed reproach of "repeating an empty formula" which anti-selectionists are so fond of using. For, after all, an empty formula, being (by definition) a formula containing no terms, is a negative kind of expression, and if it cannot, by virtue of its vacuity, do much to advance science, it cannot, on the other hand, do any harm. But a formula which contains erroneous terms may throw us off the track altogether, and my contention is that erroneous terms exist in Mr. Cunningham's formula. R. MELDOLA.

Direction of Spirals in Horns.

IN investigating the causes of directions of various spirals, I discovered a certain law and order in the arrangement of the direction of the spiral in horns which will interest many of your readers.

(1) That in the antelopes the right-hand spiral is on the left of the head, and the left-hand spiral on the right of the head (crossed). (2) That in sheep the right-hand spiral is on the right of the head, and the left spiral on the left side of the head (homonymous, or same name). The *wild* goats agree with the antelopes in regard to the spiral direction of their horns (crossed), and the oxen agree with the sheep in cases where the spiral can be noted (homonymous). Exceptions are not numerous and not difficult to remember, but this letter is not intended to do more than record the usual rules for spiral directions in horns.

If these observations be of value in clearness of description of a difficult point, it will be a gain; and they may also prove useful in classification. By taking a corkscrew (or a right-handed spiral) in the hand, it is easy to verify on the horns themselves the direction of their spiral curves. GEORGE WHERRY.

Cambridge.

Liquid Air.

THE notion that Virgil had an idea of "liquid air" because he speaks of "liquidus aer," is like the idea that Euripides was a smoker because a line of his may have begun

τὸ βακχικὸν δώρημα δός.

But there is a very curious anticipation of Prof. Dewar's discovery in Lucian's "Vera Historia" Book ii 89. Lucian there tells us that the inhabitants of the moon drink ἀὴρ ἀποθλιβόμενος ἐς κύλικα, "air squeezed or compressed into a goblet." I do not know whether liquid air has yet been used as a beverage, but in other respects the passage seems to be an exact description of the substance in question. J. ADAM.

Emmanuel College, Cambridge, December 30, 1900.

A Nest of Young Starlings in Winter.

WHILE a friend was walking through his fields near Broxbourne on Sunday afternoon, the 6th inst., he noticed a starling flying towards an an old elm with some food in its bill, and on going up to the tree he found a nest containing young birds. No doubt they are dead by this time, on account of the severe cold and the difficulty the old birds found in obtaining food for them. R. H. F.

January 8.

SOME ANIMALS EXTERMINATED DURING THE NINETEENTH CENTURY.

WHILE the century which has just closed may fairly lay claim to the gratitude of posterity on account of the magnificent tale of zoological work accomplished during its course, it is, on the other hand, undoubtedly open to the charge of having permitted the total extermination of not a few animals, and of having allowed the numbers of others to be so reduced that their disappearance, at least as truly wild creatures, can scarcely be delayed very many years longer. Possibly, if not prob-

ably, the sweeping away of the enormous herds of many species, like those of the American bison, may have been an inevitable accompaniment of the march of civilisation and progress; but there is no sort of excuse to be made for the fact that in certain instances naturalists failed to realise that species were on the very verge of extermination, and that they were actually allowed to disappear from the world without being adequately represented in our museums. Nor is it by any means certain that even the present generation is altogether free from reproach in this matter, although it cannot be said that any species hovering on the verge of extermination are absolutely unrepresented in collections. Whether, however, sufficient specimens of such species are being preserved for our successors may be an open question.

It is not our intention in this article to allude to the host of animals whose numbers have been reduced in such a wholesale manner during the century as to render them in more or less immediate danger of impending extermination, but to confine our attention in the main to those on whom this fate has already fallen. And here it may be mentioned with satisfaction that India enjoys a remarkably good record in this respect, for, so far as we are aware, it has not lost a single species of mammal, bird or reptile, either during the nineteenth century or within the period of definite history. It is true that the numbers and range of the Indian lion have been sadly curtailed during the last fifty years, and that if steps are not promptly taken for its protection that animal may, ere long, disappear from the Indian fauna. But, at any rate, it has not done so at present; and even were it exterminated in the country, this would not mean the extermination of a species, and possibly not even of a local race, since it is not improbable that the Persian representative of the lion (which is still abundant) may not be distinguishable from the Indian animal. Of large animals peculiar to India, perhaps the great Indian rhinoceros is the one that requires most careful watching in order that its numbers and its range may not be unduly reduced before it is too late to take adequate measures for its protection. And in this connection it is perhaps legitimate to call the attention of sportsmen and native princes to the urgent need of a fine specimen of this magnificent animal for the collection of the British Museum.

We have said that the century is responsible for the extinction of no inconsiderable number of the world's animals. But it must not for one moment be supposed that, within the historic period, no such exterminations by human agency had taken place in previous centuries. We have to go back so far as the year 1615 for the last evidence of the existence, in a living state, of the great flightless rail (*Aphanapteryx*) of Mauritius and Rodriguez; while the journal of the mate of the *Berkley Castle*, in 1681, is the last record of the dodo being seen alive. Again, the tall and flightless solitaire of Rodriguez is not definitely known to have been met with by Europeans after 1691, although there is some evidence to indicate that it may have lingered on in the more unfrequented portions of the island till as late as 1761. Of the extinct géant, or Mauritian coot (*Leguatia*), we have no evidence of its existence subsequent to 1695; while our last record of the crested parrot (*Lophopsittacus*) is as far back as 1601. Again, the great northern sea-cow (*Rhytina gigas*), which was only discovered on the islands of Bering Sea in the year 1741, had entirely ceased to exist by about 1767. Moreover, the giant tortoise of Réunion appears to have ceased to exist on its native island previous to the dawn of the nineteenth century, although at least one exported example has survived till our own day.

Neither can the nineteenth century be held responsible for the extermination of the South African blaauwbok (*Hippotragus leucophoeus*), a smaller relative of the familiar roan antelope, since the last known example is believed to have been killed in or about the year 1799. It had always a curiously restricted habitat, being confined to a small area in the Swellendam district.

On the other hand, the great auk is a bird whose loss we owe to the carelessness of the naturalists of the middle of the nineteenth century, for there is little doubt that if protective measures had been taken in time it might have been alive at the present day. From the American side of the Atlantic it probably disappeared somewhere about the year 1840; while the summer of 1844 witnessed the destruction of the last European pair of this remarkable bird, the last British representative having been hunted to death in the neighbourhood of Waterford Harbour ten years previously.

One of the most sad stories of extermination, and that, too, at a comparatively recent date, is revealed in the case of the South African quagga. According to Mr. H. A. Bryden, who has devoted a great deal of attention to the subject, the extermination of this zebra-like species in the Cape Colony took place between the years 1865 and 1870, and probably between the latter year and 1873 in the Orange River Colony, which was its last stronghold. The extermination of this species may be attributed entirely to the pernicious trade of hide-hunting, for in the first half of the century it was to be met with in thousands on the grass *veldt*, and formed the staple food of the Hottentot farm labourers of the Graaf Reinet and many other districts. What makes the matter still more melancholy is that specimens of the animal could easily have been procured in any numbers, both for our menageries and our museums, but that (probably owing to the circumstance that naturalists were ignorant of its impending fate) no steps were taken in the matter. In the year 1851 a female was purchased by the Zoological Society of London, while seven years later a male was presented to the same body by the late Sir George Grey. The latter survived till 1872, and was thus one of the last survivors of its race. Although the fact of the practical accomplishment of the extermination of the species at that time appears to have been unknown in London, the skin of Sir George Grey's specimen was luckily preserved, and may now be seen mounted (albeit in a somewhat worn and faded condition) in the British Museum as the solitary representative of the species. Fortunately the skeleton of this specimen was likewise preserved for the national collection.

Several photographs of the above-mentioned individual are in existence, and the Royal College of Surgeons possesses a small oil-painting, by Agassiz, of one of a pair of quaggas which were driven in harness by Mr. Sheriff Parkins in Hyde Park early in the nineteenth century. Of these two animals the College likewise possesses the skulls, which were acquired with the collection of Mr. Joshua Brookes on its purchase in 1828.

In addition to Sir George Grey's specimen, the British Museum formerly had the skin of a young quagga, in very bad condition, which was presented by the traveller William Burchell, and was subsequently described by Hamilton Smith as a distinct species, under the name of *Hippotigris isabellinus*. Apparently London museums possess no other relics of this lost species, of which, however, we believe there is an example in the museum at Edinburgh. As the animal yielded no trophies worthy the attention of the sportsman, it is unlikely that there are any specimens in private collections, unless, perchance, a skull or two may be in existence. The lack of other relics of such a common species affords a signal instance of lost opportunities, and should serve as a warning against our permitting a similar remissness to occur in the case of any other species threatened with extermination.

Mention has already been made of the extermination of the giant land tortoise of Réunion during the

eighteenth century; and in the early part of its successor four other species became extinct in the neighbouring islands of the Mascarene group, namely, *Testudo indica*, *T. triserrata* and *T. inepta* in Mauritius, and *T. vosmaeri* in Rodriguez. It has likewise been considered probable that the thin-shelled tortoise (*T. abingdoni*), of Abingdon Island, in the Galapagos group, is also no longer existing, although it was certainly alive as recently as 1875.

Of birds that have disappeared during the century, in addition to the great auk, reference may first be made to the black emeu (*Dromaeus ater*), of Kangaroo Island, South Australia. When this island was explored in 1803 by a French expedition these birds were abundant, and three were sent home to Paris, where a pair lived till 1822. On their death, the skin of one and the skeleton of the other were mounted for exhibition in the Paris Museum, where they still remain. Of the third specimen no record was obtainable till 1900, when, as already noticed in this journal, its skeleton was discovered by Prof. Giglioli in the museum at Florence. These three priceless specimens are the only examples of a species which became extinct in the native state previous to the death of the Paris pair, and before it was even known to be different from the larger emeu of the mainland. For it appears that some years after the visit of the French expedition (to which Péron was naturalist) to Kangaroo Island, a settler squatted there and forthwith set to work to make a clean sweep of the emeus and kangaroos—a task in which he was only too successful.

Before the middle of the century another large bird appears to have made its final exit from this world. When Steller discovered the northern sea-cow in the islands of Bering Sea, he also brought to the notice of science a new species of cormorant (*Phalacrocorax perspicillatus*), which was especially interesting on account of being the largest representative of its kind, and likewise by the bare white rings round its eyes and the brilliant lustre of its green and purple plumage. Stupid and sluggish in disposition, Pallas's cormorant, as the species is commonly called, appears to have been last seen alive about the year 1839, when Captain Belcher, of H.M.S. *Sulphur*, was presented with a specimen by the Governor of Sitka, who also forwarded other examples to Petersburg. Captain Belcher's specimen is preserved in the British Museum, and three other skins are known to be in existence elsewhere.

The great white water-hen (*Notornis albus*), formerly inhabiting Lord Howe and Norfolk Islands, must be added to the defunct list. And the same is the case with the Tahiti rail (*Prosobonia leucoptera*) and Latham's white-winged sandpiper (*Hypotaenidia pacifica*), the latter of which in Captain Cook's time was abundant in the island above named, as well as in the neighbouring Eimeo. The New Zealand quail (*Coturnix novaezealandiae*) is likewise entered in the British Museum list as extinct. The beautiful "*Pigeon hollondais*," so-called from its plumage presenting the Dutch colours, and technically known as *Alectoroenas nitidissima*, is a Mauritian species whose extermination probably took place during the century. It is known solely by three examples, one of which is preserved at Port Louis, the second in Paris, and the third in Edinburgh.

Nor must we omit from our list two species of Kaka parrot, one of which (*Nestor productus*) was a native of Philip Island, while the home of the second (*N. norfolcensis*) was the neighbouring Norfolk Island. A species of parraquet (*Palaeornis exsul*), peculiar to the island of Rodriguez, is also believed to be exterminated.

Neither has the duck family escaped, for the well-known pied duck (*Camptolaemus labradorius*), an ally of the eider from the North Atlantic coast of America, appears in the defaulters' list, the last-known example having been killed in 1852.

Passing on to Passerine birds, a notable loss is the handsome crested pied starling, *Fregilupus varius*, which is believed to have become extinct about the middle of the century. Of the few remaining examples of this striking species one is preserved in the British Museum. Another species, exterminated within approximately the same period, is the gorgeous black and gold mamo, or sicklebill (*Drepanis pacifica*), of Hawaii, whence it was first brought to Europe by Captain Cook. As narrated in the "Birds of the Sandwich Islands," by Messrs. Scott Wilson and Evans, the extermination of this beautiful species is to be attributed to persecution for the sake of its yellow feathers, which were used for the cloaks of the native chiefs. About four specimens are known to be preserved in museums.

Of birds that have been locally exterminated, such as the burrowing petrel (*Œstrelata haesitata*), known in the Antilles as the diablotin, it is not our intention to speak on this occasion. And this article may accordingly be fitly brought to a close by an extract from Prof. A. Newton's "Dictionary of Birds," referring to two instances where species may have perished within the century without having ever come definitely under the notice of ornithologists. After stating that one Ledru accompanied an expedition dispatched by the French Government in 1796 to the West Indies, the Professor proceeds to observe that this explorer "gives a list of the birds he found in the islands of St. Thomas and St. Croix. He enumerates fourteen kinds of birds as having occurred to him then. Of these there is now no trace of eight of the number; and, if he is to be believed, it must be supposed that within fifty or sixty years of his having been assured of their existence they have become extinct. . . . If this be not enough we may cite the case of the French islands of Guadeloupe and Martinique, in which, according to M. Guyon, there were once found six species of Psittaci, all now exterminated; and it may possibly be that the macaws, stated by Gosse and Mr. March to have formerly frequented certain parts of Jamaica, but not apparently noticed there for many years, have fallen victims to colonisation and its consequences." R. L.

CLIMBING IN THE HIMALAYAS.[1]

DURING an extended cycling tour in the East, the authors spent the summer months of 1898 and the following year in the Himalayas. In the former season they penetrated from Srinagar, which they had reached on their vehicles, into the mountains of Ladakh, Nubra, and Suru, and, later on, into Sikkim from Darjeeling. Next year they took with them Matthias Zurbriggen, who had been guide to Sir Martin Conway on his memorable journey in 1892, retracing his steps up the Biafo Glacier to the Hispar Pass, and then making some important ascents in the district about the Skoro La Pass. Altogether they were encamped for many days at altitudes not less than 16,000 feet, crossed several passes more than a thousand feet higher, and made the ascent of three virgin icy summits, rising to heights of 18,600, 19,450, and 21,000 feet respectively. Thus Mrs. Workman not only is the first of her sex to do serious mountain work in the Himalayas, but also has been higher than any of them above sea-level.

Climbing in the Himalayas, as the authors remark, is a much more serious affair than in the Alps. The glaciers and peaks, as shown by the excellent illustrations, one of which is appended by the courtesy of the publisher, are certainly not less difficult; roads are often wanting, mountain inns and chalets always; the camp

[1] "In the Ice World of Himalaya, among the Peaks and Passes of Ladakh, Nubra, Suru, and Baltistan." By Fanny Bullock Workman and William Hunter Workman, M.A., M.D. With three maps and sixty-seven illustrations. Pp. xvi + 204. (London: T. Fisher Unwin, 1900.)

must be pitched far away from even the smallest of towns; provisions, wraps, tents, all requisites, must be transported by human labour, which is costly and entails endless difficulties. The misdeeds of porters were once a stock subject of complaint among alpine climbers, but the worst of them are surpassed by Indian coolies, who are ill-fed, ill-clad and without mountain experience, while the native servants, almost universally, are adepts in cheating and mendacity. Through their misconduct one expedition, that into Sikkim, was a complete failure; and on this occasion the travellers apparently had good reason to complain of the British Political Officer at Darjeeling—not the one, it may be observed, whose courtesy Mr. D. Freshfield experienced on his tour round Kinchinjanga.

On the second year's journey they plunged more deeply into the Himalayan ice world. After reaching Askole by the Skoro La Pass, nearly 17,000 feet above sea-level, they ascended the Biafo glacier, which had shrunk and changed since 1892, to the Hispar Pass, from which they obtained splendid views of the neighbouring snowy giants, afterwards returning to Askole. Again leaving it they pitched a camp above the Skoro La Glacier, 16,200 feet from sea-level, at which, or a higher one, they remained for six days. From it they ascended the Siegfriedhorn, an excellent point of view 18,600 feet high, and the snowy Mount Bullock Workman, 19,450 feet. Returning over the Skoro La Pass they struck up the Shigar Valley, and finally, from a camp 17,900 feet above sea-level, reached, in unfavourable weather, the summit of Koser Gunge, about 21,000 feet.

The book is pleasantly written, though we cannot think such words as "itemized" and "motived" valuable additions to the English language. In addition to vivid descriptions of the scenery, it records, though professedly a work on mountain travel, some facts of scientific interest. The authors, like all recent travellers in the higher Himalayas, were struck with the signs of rapid disintegration. The great changes of temperature shatter the rocks, and strew the mountain flanks with fragments, forming huge slopes of débris and great alluvial fans. On one occasion they had a rather narrow escape when "a mixture of solid and semi-solid bodies," consisting of "mud and stones of every size, some of them many tons in weight, which were rolled on one another as if they were pebbles, poured down a glen, sweeping everything before it"—a mass twenty to thirty feet in height and some sixty yards in breadth. The work of mountain sculpture evidently proceeds more rapidly in the Himalayas than in the Alps. Yet there was probably a time when the latter passed through a similar stage. Mud glaciers, if the phrase be permitted, are not unknown in them, but much material, often hastily classed as moraine, is really of very composite origin, and is transported more by water than by ice.

The last chapter of the book, which gives a summary of their experiences of the effects of diminished atmospheric pressure, has a special value because Dr. Workman can speak as a medical expert. They lived for many days at heights between fourteen and seventeen thousand feet, sleeping several times in camps between sixteen and eighteen thousand feet, and thrice reached elevations between the last and twenty-one thousand feet. Their experiences agree generally with those of Whymper, Conway, FitzGerald and Vines. Below 15,000 feet Dr. Workman noticed no great departure from the normal. In the higher camps he slept well, though Mrs. Workman did not; they had good appetites, neither suffered from mountain sickness or, with one exception in each case, from headache, and this they attributed to cold rather than diminished atmospheric pressure; but both, like all their predecessors, felt the effects of the latter increasingly perceptible after rising above some 16,000 feet. They made slower progress, got more readily out of breath, and from about 18,000 feet upwards found that all movements, even stooping or altering the position when at rest, had to be made with deliberation—even holding the breath for a moment to take a snap-shot with the camera was followed by gasping. But by accommodating themselves to the conditions they climbed without severe discomfort, and did not find that

FIG. 1.—Siniolehum, Sikkim.

this materially increased in the ascent to the highest point attained. The commissariat, in Dr. Workman's opinion, is a most important factor for success in reaching great elevations, since he holds dyspepsia and imperfect nutrition responsible for the distressing symptoms experienced by some of his predecessors. Food should be rather light, but nutritious. He makes some valuable remarks on the best kinds, stating that he thinks alcohol beneficial if it be taken in very moderate quantities and at meal times; warm wraps also are most important. In fact, his careful discussion of the subject is a valuable supplement to what has been already published, and proves that climbers anxious to reach the highest summits of Asia must possess either the *dura messorum ilia* or the purse which can bear the very heavy cost of a well-equipped expedition. T. G. BONNEY.

THE ROYAL INDIAN ENGINEERING COLLEGE.

FROM letters which have been published recently in the *Times* and other journals, we have become aware of the following facts relating to the Royal Indian Engineering College, Coopers Hill:—

(1) The Secretary of State for India, acting on certain suggestions, made to him ostensibly by the Board of Visitors of the College, for remodelling the course of instruction on a very extensive scale, decided, some considerable time back, that it was necessary to dismiss *half the educational staff* of the College for the purpose of "reducing the present excessive cost of the staff and increasing the efficiency of the teaching."

(2) No hint that this momentous change was coming was conveyed to any of the seven gentlemen concerned, who received their first intimation on the 17th of last month from the President of the College, Colonel J. W. Ottley, in a letter of singular abruptness, heartlessness and irony. This letter, addressed to each of the seven gentlemen, was as follows:

"Sir, I have the honour to forward for your information a copy of a letter, P.W. 2531, dated 14th inst., from which you will see that I am instructed to convey to you the decision of the Secretary of State for India in Council that you will be required to vacate your appointment at this College at the end of the next Easter term.

"I have the honour to be, Sir, your obedient servant,
"JOHN W. OTTLEY, President, R.I.E.C."

The seven gentlemen to whom this communication was made are Mr. T. A. Hearson, M.Inst.C.E., Professor of Hydraulic Engineering, &c.; Mr. H. McLeod, F.R.S., Professor of Chemistry; Mr. W. N. Stocker, M.A., Professor of Physics; Mr. A. H. Heath, Assoc.M.Inst.C.E., Assistant Professor of Engineering; Mr. T. Shields, M.A., Demonstrator in Physics; Mr. P. Reilly, Demonstrator, Mechanical Laboratory; Mr. J. C. Hurst, Lecturer in Accounts.

With reference to the first of these facts we may affirm with confidence that the drastic changes—which involve serious curtailments of the branches of engineering and chemistry, and, apparently, the total abolition of physics and electrical engineering—are not to be attributed to the Board of Visitors. It is not credible that these gentlemen—very busy men as some of them are—can have devoted so much time and study to the educational course of the College as to justify their taking the responsibility of advising the Secretary of State for India to effect such extensive changes. We are compelled to adopt the conclusion that Colonel Ottley (whose name appears for the first time in the College Calendar for 1899-1900) himself is the real author. If this is so, we are further compelled to inquire into Colonel Ottley's qualifications as an educationist and a man of science. We are not acquainted with any scientific treatises or papers of his authorship, nor are we aware that he was selected as the head of a scientific college because of any experience as a lecturer on scientific subjects. His predecessors at the College have been, we believe, like himself, officers of Royal Engineers; but, apparently, they were wise enough to keep their theoretical autocracy as presidents within the limits prescribed by common sense.

From the memorial addressed by the dismissed members of the staff to the Secretary of State we infer that Colonel Ottley interprets his autocracy very literally, and is disposed to take no advice from the educational staff on matters of which they must necessarily know vastly more than he; and if so, it ought to be abundantly clear to the India Office that Coopers Hill College must be, as an educational institution, a complete failure.

It will be observed that the subjects which are most affected by the change—chemistry, physics and the mechanical laboratory—are those in which practical work has an important place; it is well known to those experienced in scientific education that this practical work is of the greatest value in developing in students the scientific spirit which is so essential to success in such a profession as engineering. We believe that the laboratories at Coopers Hill were enlarged some years ago and the staff increased, so that every student should have instruction in the chemical, physical and mechanical laboratories, on the recommendation of the Board of Visitors; but at that time one of the members of the Board was Sir William Siemens, who, knowing the result of practical work in the German universities upon industries and professions, considered its further development at Coopers Hill to be of importance. The present action appears to be in direct opposition to the former recommendations of the Board of Visitors.

Turning our attention next to the second of the above facts, we are compelled to express not only astonishment but indignation that such heartless brutality should have been possible in England. To know that seven gentlemen—two of them members of the Institution of Civil Engineers and another a Fellow of the Royal Society—are to receive a three months' notice of dismissal, timed, as it would seem, by the clock; to know that it must be of the utmost importance to them to be warned of the impending catastrophe so that they may have opportunities for seeking other work; and yet to keep their sentence a dead secret until the last available moment, constitutes a condition of mind which, we hope, is very rare among Englishmen.

The cause of Coopers Hill College is, in this matter, the cause of education at large. All that the dismissed members of the staff have asked from the India Office is that an independent committee of experts in scientific engineering, education, and college management should be appointed to inquire into the way in which the College is managed.

But we go beyond this request. We would make an appeal to men of science and of learning to make, either by deputation or by memorial, a representation to the India Office of the widespread feeling of disapproval with which this official action, for which the Secretary of State for India is responsible, is regarded, and of the desirability of ensuring to the educational staff of the College at Coopers Hill such influence in educational matters as is accorded in every College in the Kingdom.

NOTES.

PROF. STRASBURGER has been elected a correspondant of the Paris Academy of Sciences, in the section of botany.

THE death is announced of Dr. Potain, professor of medicine in the University of Paris, and member of the section of medicine and surgery of the Paris Academy of Sciences.

IT is announced by *Science* that Prof. W. W. Campbell has been appointed director of the Lick Observatory, in succession to the late Prof. J. E. Keeler.

AT a special meeting of the Metropolitan District Railway Company on Monday, it was resolved that capital should be raised for the purpose of adapting the line to electric traction. This action has been forced upon the company by the diversion of traffic to the Central Electric Railway, and omnibus competition.

WE regret to announce the death of Dr. G. Pacher, of Padua University, on December 29, at the age of thirty-three. We owe to him some valuable studies of the records of the Vicentini microseismograph, and also the application of the pantagraph to that instrument.

THE Board of Trade have appointed a committee consisting of Lord Rayleigh, F.R.S., chairman, Sir John Wolfe-Barry, K.C.B., F.R.S., and Prof. Ewing, F.R.S., to consider to what

extent the working of the traffic on the Central London Railway produces vibration in the adjacent buildings, and what alterations in the conditions of such working or in structure can be devised to remedy the same.

THE dispute between Kew Observatory and the London United Tramways Company still occupies public attention. Mr. R. T. Glazebrook, in a letter to the *Times*, gives an answer to the argument brought forward by the Tramways Company that the current leaking into their lines, presumably from the Central London Railway, should have already vitiated the magnetic observations made at Kew. He points out that the observations have not been appreciably affected, and that from theoretical considerations it was not to be expected that they would be. The disturbances that the London United Tramways Company are likely to produce will be about a hundred times as serious. Mr. Glazebrook has given a proof of this in a letter to the *Electrician*. A letter to the *Times* from Mr. Walter Hunter points out that the leakage currents from the tramway lines are a serious danger to gas and water pipes, and that the amount of harm done is merely a question of time. Perhaps it is too much to expect the Tramways Company to consider any but their own interests; it is to be hoped, however, that they will be brought to see that it is really to their own interest to insulate their return mains. There is no difficulty in doing so, and sooner or later it will have to be done. We notice that American experience shows that the only way to avoid electrolysis of the pipes is to keep the return currents out of the ground, and also that an experience from ten years running of over 200 miles of track shows that the double trolley system—which the London United Tramways Company consider impracticable—is cheaper in operation and maintenance than the single trolley system.

THE annual general meeting of the Royal Meteorological Society will be held on Wednesday, January 16, when the president, Dr. C. Theodore Williams, will deliver an address on "The Climate of Norway and its Factors."

THE *British Medical Journal* states that the Astley Cooper triennial prize of 300*l.* will be awarded for the best essay or treatise on "The Pathology of Carcinoma and the Distribution and Frequency of the Secondary Deposits corresponding to the Various Primary Growths." The essay, which is to be written in English, must reach Guy's Hospital, addressed to the physicians and surgeons, on or before January, 1904.

COL. A. T. FRASER sends us a copy of the *Indépendance Belge* to direct our attention to a matter brought before the last meeting of the Brussels Academy of Sciences. From the report we see that M. Charles Lagrange, director of the Royal Observatory, has resigned his office and has presented to the Academy his two years' arrears of salary, or a capital sum of ten thousand francs, to establish a prize to be awarded, at intervals of four years, for the best contribution to our knowledge of the physics of the globe. In expressing the thanks of the Academy for the gift, General Brialmont described the circumstances which led to M. Lagrange's resignation. It appears that for the past two years the position of director of the Observatory has been a humiliating one, because a young infantry officer without scientific attainments has controlled the establishment.

WE regret to announce the death of Mr. F. W. Egan, B.A., of the Geological Survey of Ireland, which took place at his residence in Dublin on January 6. After some experience as a civil engineer, he joined the Geological Survey under Jukes in 1868, and has ever since that date been actively engaged in the field-work of the service. For the last few years he devoted himself to the revision of the Silurian system in the east of Ireland, and separated the Lower from the Upper division over a large part of that region. Eighteen months ago, during a tour of inspection in County Wicklow, the Director-General of the Survey, with Messrs. Egan and McHenry, were thrown from an Irish car. Though each of the party sustained more or less injury, Mr. Egan fared worst. He had his shoulder dislocated, and suffered also some internal injury, so that he never regained his former strength, though he went through the field-campaign last year. Last week, symptoms of a grave kind began to show themselves, and he passed away on Sunday evening. Quiet, gentle and kindly, and not without a touch of humour, he was everywhere a favourite, and though he never had any ambition to distinguish himself, his long years of steady and patient devotion to his official duties enabled him to do good service to the cause of geology in Ireland.

THE Berlin correspondent of the *Times* announces that the German Emperor has conferred the Order of the Red Eagle, First Class, upon Lieutenant-General Count von Zeppelin, as a recognition of his efforts to overcome the difficulties of aërial navigation. The announcement of this distinction was made to Count von Zeppelin by the following letter from the Emperor, which was conveyed to him by General von Hahnke, the chief of the Emperor's Military Cabinet, before the beginning of a lecture upon the "Future of Aërial Navigation," delivered by the aëronaut at a meeting of the Berlin branch of the German Colonial Society:—"Having been informed of the ascents which have been made in the air-ship which you have invented, I am glad to express my appreciation of your persistence and trouble in successfully carrying out your self-imposed task, in spite of the manifold difficulties which it presented. The advantages of your system—the division of the long, extended balloon into compartments, the equal distribution of the burden by means of two independent engines, and a rudder working with success for the first time in a vertical direction—have enabled your air-ship to move with the greatest speed which has hitherto been attained and have rendered it amenable to the rudder. The results which you have achieved constitute an epoch-making step in advance in the construction of air-ships, and form a valuable basis for further experiments with the existing material. I will support you in these further experiments by placing the advice and the experience of the Balloon Division of the army at your disposal whenever you may desire. I have accordingly given orders to the Balloon Division to send an officer to be present at your future experiments whenever it may be of advantage. As an outward sign of my recognition I hereby confer upon you the Order of the Red Eagle, First Class."

THE annual general meeting of the Institution of Mechanical Engineers will be held on Friday evening, January 18, when the chair will be taken by the president, Sir William H. White, K.C.B., F.R.S. The first presentation by the Institution of the Willans Premium will be made to Capt. H. Riall Sankey; and the prizes awarded by the Council for the best two papers in the graduates section will be presented to Mr. W. B. Cleverly and Mr. Brees van Homan. The adjourned discussion will be resumed upon the paper on power-gas and large gas-engines for central stations by Mr. Herbert A. Humphrey, read at the December meeting. At the graduates' meeting, to be held on Monday, January 14, Prof. J. A. Ewing, F.R.S. will deliver a lecture at the Institution on "The Structure of Metals," illustrated by lantern slides.

ENTOMOLOGY has sustained a serious loss in the death of Mr. John Henry Leech, which occurred on December 29, at the early age of thirty-eight. Mr. Leech, who had one residence at Hurdcott House, Salisbury, and a second at Kippure Manor, Kilbride, Dublin, was the eldest son of the late Mr. John Leech, of Gorse Hall, Cheshire, and was a graduate of Cambridge. In addition to being proprietor of the *Entomologist*, he was author of "The Butterflies of China, Japan and

Corea," a work for which he accumulated a large collection (part of which is now in the Natural History Museum) during his travels in the countries mentioned. If, as seems probable, his premature death was due to hardships and exposure during those travels, his name may be added to the list of martyrs in the cause of science. Mr. Leech was elected a fellow of the Zoological Society in 1885, and was likewise a fellow of the Linnean and the Royal Geographical Societies.

THE fall of two of the stones of the outer circle of Stonehenge, on the last evening of the nineteenth century, directs attention to the necessity for at once taking steps to preserve this remarkable prehistoric monument. The stones ought to be replaced while their original positions are clearly remembered, and before public interest in their fall has subsided. An engineer, writing to the *Times*, suggests a method of undermining the stones and imbedding them in a foundation of concrete or cement. A scheme of this kind would cost comparatively little, and there should be no difficulty in obtaining funds to carry it out. At any rate, the preservation of Stonehenge ought to be given serious consideration without delay, and archæologists should see that something is done to prevent the gradual collapse of this wonderful memorial of the past.

As already announced, a committee of the U.S. House of Representatives has decided to report in favour of the adoption of the metric system of weights and measures. Referring to this, the *Scientific American* makes the suggestion that England should join with the United States in introducing the system at the same time. Our contemporary remarks:—"The probability of the Bill's becoming a law would be greatly increased if the other great branch of the English-speaking race could be induced to make the change simultaneously with this country. The agitation in favour of the metric system is as strong, possibly stronger, in Great Britain as it is here, and in view of the close trade relations and the enormous volume of business between the two countries, it is well worth considering whether an attempt at concerted, or rather simultaneous, adoption of the metric system would not be advisable."

THE Brussels correspondent of the *Times* states that arrangements are in progress for a series of experiments in wireless telegraphy between Brussels and Antwerp, on the Guarini system. The apparatus for transmitting messages is nearly complete in both cities, and has been erected in Brussels in the Place du Congrès and at Antwerp on the tower of the well-known cathedral of Notre Dame. M. Guarini is doubtful whether local conditions will admit of direct communication, and he proposes to utilise Malines Cathedral, situated midway between the two cities, as an automatic repeating station. On the other hand, if it is found practicable, Antwerp itself will be made to serve as a repeating station for other points of the compass. The first trial is to take place on January 20.

DURING the past week the type of weather over the British Islands has entirely changed, the warm south-westerly current having given way to cold north-easterly winds, with high barometric pressure. During the latter part of last week the change of conditions caused a large amount of fog, especially over the southern parts of England, but this was quickly dispelled by a piercing N.E. gale which set in on Saturday evening, and was in turn followed by considerable falls of snow. The temperature was lowest over the midland and southern parts of the kingdom, where readings exceeding 10° below the freezing point have been recorded. This spell of wintry weather has spread over this country from the Continent, where conditions during the week have been abnormal. In Germany the thermometer has fallen below zero, and in France readings of 20° below the freezing point have been registered. Snow has fallen in many parts, and also in Rome for the first time during the last seven years. A rise of temperature occurred over the southern portion of England on Wednesday.

IN the U.S. *Monthly Weather Review* for September last, Mr. H. M. Watts discusses what he calls the Gulf Stream myth. He points out that the mild climate of north-western Europe is not due to the Gulf Stream, but to the prevailing eastward and north-eastward drift of the atmosphere which distributes over Europe the heat conserved by the whole Atlantic Ocean north of latitude 35° (roughly). The Gulf Stream is not distinguishable in temperature or "set," the author states, from the rest of the ocean, by the time it gets east of Newfoundland; and if it were by any possibility to be diverted at the Straits of Florida, no one in England would be a whit the wiser. If the drift of the aërial currents were reversed, the Atlantic Coast States, from North Carolina to Newfoundland, would have the mildness of Bermuda, not on account of any one ocean current, but because of the conserved warmth of the ocean as a whole. As it is, the August hot waves, the mild spells in January and February, and other anomalies which seem at times to reverse the seasons on the eastern coasts of the United States, are due, not to any shifting of the Gulf Stream, but to the intrusion of the anticyclone (or system of high barometric pressure) from the Atlantic Ocean.

WE have received the report of the Economical Society of Livonia, containing the results of the rainfall and air-temperature observations made at some 150 stations in the Russian Baltic provinces during the year 1899. The stations are maintained partly by the Central Physical Observatory of St. Petersburg and partly by the Ministry of Marine, and, to a considerable extent, the monthly and yearly results are included in the publications of the Central Observatory. The Society does good work in establishing a close network of stations, and in publishing the results in more detail than is generally done in the official year-books. The observations have been utilised during the time of harvest by the issue of special forecasts to agriculturists, and such a system is of great utility in endeavouring to discover the various anomalies that are found to exist in the distribution of rainfall, which cannot always be explained by the geographical conditions of the stations.

AN interesting contribution to our knowledge of the laws of vortex motion is given by Herr K. Żorawski in the *Bulletin* of the Cracow Academy, viii., 1900. The deduction of these laws from the equations of hydrodynamics, subject to certain physical assumptions, is mainly due to Helmholtz; the present paper deals with the converse problem of finding the mathematical conditions which must be satisfied by the velocity components in order that the so-called "circulation theorems" may hold good.

UNDER the title of "The transfigurations of a Science," Prof. Gino Loria has published a reprint of his academical address to the University of Genoa, dealing with the history of mathematics. It traces the gradual progress of mathematics from the ancient Greeks to the present day; the introduction of algebra into Europe, the fusion of the two branches of mathematics, algebra and geometry by the creation of analytical geometry; and, lastly, the rising up of the science of non-Euclidian geometry.

UNDER the name of "The Astronomical Demonstrator," Mr. W. H. Adams, of Wandsworth, has recently arranged a series of lecture-models intended to provide a teacher with the means of quickly illustrating, in a practical manner, most of the dispositions and phenomena of the solar system. A large sheet of cardboard or other material is provided with diagrams of the orbits of the planets, &c., and small models of the sun, earth,

moon and planets, with weighted bases and movable axes, are placed in their proper positions on their various orbits as determined from an ephemeris. In addition, there are various appendages capable of attachment to the objects for the illustration of special phenomena, such as eclipses of the sun and moon. The apparatus should be specially useful in classes where it is possible to allow the pupils to individually work exercises in the proper grouping of the planets, as in that way many of the definitions connected with orbital motion are presented in a very simple manner.

A VALUABLE contribution to the climatology of Africa appears in the *Mitteilungen aus den deutschen Schutzgebieten* in the form of records obtained from self-registering meteorological instruments in German East Africa. The period covered extends from the end of 1895 to the end of 1899, and the records, more or less complete in each case, are from the seven stations Dar-es-Salam, Tanga, Kwai, Tosamaganga, Tabora, Kibosho and Muansa.

THE *Zeitschrift der Gesellschaft für Erdkunde zu Berlin* contains an important article on the question of glaciation in the Central Balkans by Prof. W. Götz. The author's investigations support the conclusions that (1) after diluvial deposits had been laid down in the mountain valleys, the erosive action of the streams greatly increased, probably on account of sinking of the lower courses; (2) the apparent indications of glacial action met with are false; and (3) traces of glacial phenomena are absent where they ought to be most marked, at the higher elevations in regions suited to the formation of snow-fields.

THE Oregon mountaineering club, which has adopted the title *Mazama*, the Indian name of the mountain goat, has just issued the first number of the second volume, or, rather series, of its journal. The number is devoted to Mount Rainier, and includes an account of the expedition of the club to that mountain in 1897. Observations of the mercurial barometer, made at the summit by Prof. Edgar McClure, who lost his life by a fall during the descent, have been reduced by Prof. E. H. M'Allister, and give the height of Mount Rainier at 14,528 feet, compared with 14,519 feet obtained by the United States Geological Survey.

IN an article on the Phyllades of the Ardennes compared with the Slates of North Wales (Part ii. *Proc.* Liverpool Geol. Soc., 1900), Mr. T. Mellard Reade and Mr. P. Holland state their conclusions that slaty cleavage is not alone a mechanical effect, but that it is mainly due to a development of flaky minerals in conjunction with the shearing forces to which the slate rock has undoubtedly been subjected.

"THE Geology of the Country between Atherstone and Charnwood Forest" is the title of a geological survey memoir by Mr. C. Fox-Strangways, just published in explanation of the map No. 155. The pictorial frontispiece illustrates the Hanging Rocks at Woodhouse Eaves, one of those crags of sharply pointed rocks which characterise Charnwood Forest, and in some instances suggest resemblances to the kopjes of British South Africa. These ancient pre-Cambrian rocks have been studied in detail by Prof. W. W. Watts, who contributes a chapter on the subject confirming the main results attained by Prof. Bonney and the Rev. E. Hill, and adding much in the determination of an orderly succession. Mr. Strangways contributes chapters on the Stockingford Shales of Cambrian age, on the Coal-measures of parts of Warwickshire and Leicestershire, with illustrative sections and records of borings and sinkings, and on the newer deposits, Permian and Trias, Glacial and Recent. In an Appendix there is a list of works on the geology of Leicestershire, which has been compiled by Mr. Strangways with the aid of Mr. Whitaker.

TO the *Proceedings* of the Philadelphia Academy (1900, pp. 568–581) Mr. H. A. Pilsbry has recently contributed a suggestive paper on the genesis of the faunas of the middle Pacific islands. The land mollusca of these islands form the basis of the discussion, which is formulated by the author in the following words:—"Are the Mid-Pacific snail faunas witnesses to the existence of a palæozoic or early mesozoic land mass, probably continental in proportions, and peopled by representatives of nearly all land-snail groups then existing?" A further question is whether this hypothetical continent was connected at a comparatively recent epoch with Chili. It is concluded that the evidence in favour of the existence of such a continent (upon the sunken heights of which the present island-masses, volcanic or coral, have been superimposed) is overwhelming. But both the marine and terrestrial molluscs lend no countenance that this continent was ever connected with America. It is somewhat curious that the author makes no reference to the Gondwana flora, which has been considered by Blanford and others as affording evidence of a girdle of land round much of the globe in low latitudes in palæozoic or mesozoic times.

THE fourth part of vol. lxviii. of the *Zeitschrift für wissenschaftliche Zoologie* contains an important paper by Herr Antonin Stolc on the power of assimilating and producing hydrocarbons by amœba-like organisms, such as *Pelomyxa palustris*. In spite of certain experiments that have had a negative result, the author is of opinion that such a power undoubtedly exists in the species mentioned, as well as in other members of the group, and he refers to the detection by Reinke and Rodewald of glycogen in the tissues of *Aethalium septicum*. To the same issue Herr W. Redikorzew contributes the results of his investigations into the structure of the ocelli of insects and other arthropods. The ocelli are originally formed by a depression in the thick hypodermal layer, in which one of two subsequent modes of development takes place.

PARTS x to xix of "Papers from the Harriman Alaska Expedition," all of which are devoted to the entomological results (including Arachnids), have been received. Mr. N. Banks deals with the Neuropteroid insects and Arachnida, Mr. H. G. Dyar with the Lepidoptera, Mr. O. Heidemann with the Heteroptera, Mr. T. Kincaid with the Sphegoids and Vespoids, while Mr. A. N. Caudell is responsible for the Orthoptera, Mr. T. Pergande for the Aphididæ and Formicidæ, and Mr. E. A. Schwarz for the Coleoptera and the Psyllidæ. The beetles are the group which had been most worked previously; only a single species of Orthoptera was obtained; but in most of the other groups a considerable number of new types were collected.

THE January number of the *Journal of Conchology* contains a list of British Marine Molluscs and Brachiopods, prepared by a committee of the Conchological Society. This is a good start for the new century, the nomenclature having been thoroughly revised and brought up to date. Some of the names, such as *Neptunea antiqua* for the red whelk, may be unfamiliar and strange, but it is to be hoped that in future they may, for the sake of uniformity, be adopted by all.

ADDITIONS to the British insect fauna continue to be made from time to time, the *Entomologist's Monthly Magazine* for January recording two kinds of saw-flies as new to our islands, while it also gives a list of species of beetles added to the list during 1899 and 1900.

REVIEWING the recent report on the working and results of the Woburn Experimental Fruit Farm, Dr. Maxwell Masters suggested (p. 178) that it would be an advantage to make a corresponding series of growths on poor soil, so as to afford a basis for comparison. We now learn that such a control station has been established already on a relatively barren soil; but the

installation is too recent to allow any definite inferences yet to be drawn.

MESSRS. W. N. BRUNTON AND SON, Musselburgh, N.B., have issued a new list of special brands of electrical resistance material. Taking the electrical resistance of copper as unity, the resistances of wires supplied by the firm are given as follows: Pure Swedish iron, 6; soft steel, 8; Edina steel, 12; German silver (19 per cent.), 17; German silver (28 per cent.), 26; Ferno, 30; and Beacon, 51.

MESSRS. CHAPMAN AND HALL have published a second edition, with appendix, of a book by Mr. F. Hovenden, bearing for its title the interrogations "What is Life? or Where are We? What are We? Whence did we come? and Whither do we Go?" Mr. Hovenden explains how he is able to answer these questions and revise the accepted opinions of men of science.

A SHORT account of the scientific work accomplished by the Tasmanian Society and the Royal Society of Tasmania, from the year 1840 to the close of 1900, has been prepared by Mr. Alex. Morton, the secretary of the latter society. The total number of scientific papers published by this society during the period mentioned, and not including small papers on various subjects, is 606. Of these no less than 132 are devoted to geology, palæontology and mineralogy, 85 to botany, 56 to astronomy and meteorology, and 53 to fishes. Mr. Morton's record is an interesting history of scientific activity in Tasmania, and it is a good testimonial to the valuable work of the Royal Society at Hobart.

THE additions to the Zoological Society's Gardens during the past week include a Macaque Monkey (*Macacus cynomolgus*) from the Andaman Islands, presented by Lieut.-Colonel G. M. Prichard, I.S.C.; a Campbell's Monkey (*Cercopithecus campbelli*) from West Africa, presented by Mr. W. R. Fowler; a Suricate (*Suricata tetradactyla*) from South Africa, presented by Mr. E. Thomas; seven Verreaux's Guinea Fowls (*Guttera edouardi*) from East Africa, presented by Mr. J. F. Walker; two Crested Pigeons (*Ocyphaps lophotes*) from Australia, presented by Mr. W. L. Prentice; two Blue-winged Sivas (*Siva cyanoptera*), a Silver-eared Mesia (*Mesia argentauris*), a White-capped Redstart (*Chimarrhornis leucocephalus*), a Rufous-bellied Miltava (*Miltava sundara*), a Burmese Roller (*Coracias affinis*) from India, presented by Mr. E. W. Harper; three Painted Snipe (*Rostratula capensis*) from India, presented by Mr. Frank Finn; a Heron (*Ardea cinerea*) from South Africa, presented by Mr. J. E. Matcham; three Delalande's Lizards (*Nucras delalandi*), a Hispid Lizard (*Agama hispida*), a Three-streaked Skink (*Mabina trivittata*), a Rufescent Snake (*Leptodira hotambaeia*), a Lineated Snake (*Boodon lineatus*) from South Africa, presented by Mr. J. D. Waley; two Green Monkeys (*Cercopithecus callitrichus*) from West Africa, three Viscachas (*Lagostomus trichodactylus*) from Buenos Ayres, three Open-bills (*Anastomus oscitans*), four Starred Tortoises (*Testudo elegans*) from India, a Blue-crowned Hanging Parrakeet (*Loriculus galgulus*) from Malacca, ten Small-scaled Mastigures (*Uromastix microlepis*) from Persia, a Common Toad (*Bufo vulgaris*), European, deposited.

OUR ASTRONOMICAL COLUMN.

ELEMENTS OF COMET 1900 (*c*).—A circular from the Centralstelle at Kiel gives the elements of this comet, computed by H. Kreutz and J. Möller from observations on December 24, 26 and 28, 1900

$$T = 1900 \text{ Dec. } 2{\cdot}660 \text{ M.T. Berlin.}$$

$$\left.\begin{aligned} \omega &= 178°\ 0'{\cdot}8 \\ \Omega &= 192\ 28{\cdot}3 \\ i &= 30\ 25{\cdot}4 \end{aligned}\right\} 1900{\cdot}0$$

$$\log q = 9{\cdot}99184$$

The brightness of the comet is slowly decreasing. The latest observation recorded is by Aitken at Lick, the position being:—

$$\left.\begin{aligned} \text{R.A.} &= 23\text{h. } 23\text{m. } 18{\cdot}5\text{s.} \\ \text{Decl.} &= -23°\ 7'\ 27'' \end{aligned}\right\} 1900 \text{ Dec. } 28.$$

Ephemeris for 12h. Berlin Mean Time.

1901.	R.A. h. m. s.		Decl. ° ′		Br.
Jan. 10	0 36 30	...	−22 44·0	...	0·68
11	41 51	...	22 36·8		
12	47 7	...	22 28·9		
13	52 20	...	22 20·4	...	0·60
14	0 57 29	...	22 11·3		
15	1 2 34	...	22 1·6		
16	7 36	...	21 51·4		
17	1 12 33	...	−21 40·6	...	0·53

NEW VARIABLE STARS.—Three more variables have been recorded as discovered in 1900, bringing the number for the year up to twenty-three (*Astronomische Nachrichten*, Bd. 154, No. 3678).

21.1900, *Monocerotis*.—Prof. W. Ceraski, writing from Moscow, announces the variability of the star situated at

R.A. h. m. s.		Decl. ° ′ ″	
6 48 49·13	...	+11 25 37·0	(1855·0)
6 51 19·24	...	+11 22 21·6	(1900.0)

The brightness varies from 8·8 to 11·5 magnitude.

22.1900, *Cygni*.—Mr. A. Stanley Williams, from examination of photographs by Prof. Max Wolf and himself, has detected variability in the star B D. + 42°·3935, having the position

$$\left.\begin{aligned} \text{RA.} &= 20^{\text{h}}\ 54^{\text{m}}\ 45{\cdot}9^{\text{s}} \\ \text{Decl.} &= +\ 42°\ 2'{\cdot}0 \end{aligned}\right\} (1855{\cdot}0).$$

The magnitude varies from 9·5 to 11·0. A table of observations from 1891 is given, from which the following elements for the variable are determined:—

Epoch of Max. = 1900 Feb. 5 + 13d. 315 E,

so that future maxima may be expected on Jan. 17 and 30, 1901. The writer draws attention to the fact that the rise from minimum to maximum is very rapid, a phenomenon previously recorded by Dr. Hartwig in the variable 2.1900 Cygni.

23.1900, *Andromedae*.—Dr. T. D. Anderson draws attention to the variability of the star B.D. + 38°·315, the place of which is

$$\left.\begin{aligned} \text{R.A.} &= 1^{\text{h}}\ 31^{\text{m}}\ 7{\cdot}9^{\text{s}} \\ \text{Decl.} &= +\ 38°\ 36'{\cdot}3 \end{aligned}\right\} (1855{\cdot}0).$$

The variation is from magnitude 9·8 (1900 Oct. 27) to 10·7 (1900 Dec. 15).

VISIBLE SPECTRUM OF NOVA AQUILÆ.—Prof. W. W. Campbell, during the autumn of 1900, made an examination of the spectrum of the new star in Aquila, which had been discovered by Mrs. Fleming in July, 1900. A 60° simple prism spectroscope was used in connection with the 36 inch Lick refractor. Prof. Campbell confirms the Harvard College observations as to the spectrum being nebular, but mentions differences between it and that of Nova Aurigæ in 1892 which are of importance. The visible spectrum is stated to consist of extremely faint continuous light in the green, and of three bright bands in the positions of the three nebular lines. The relative intensities of the three bands were in agreement with the corresponding intensities in actual nebular spectra. In addition, however, the bands were *not monochromatic*, but on the contrary were *very broad*, perhaps fully twice as broad as in the nebular spectrum of Nova Aurigæ in 1892.

NORMAL POSITIONS OF CERES.—Prof. G. W. Hill has collected the available observations of the minor planet Ceres for the past century during which it has been known, and formed normals from as many as were suitable. The computed normal positions are given for seventy-five years, the dates being for Greenwich mean noon, the values of the co-ordinates being *true*, not apparent. The planet has been observed at every opposition since its discovery, but on two occasions the reductions are discordant (*Astronomical Journal*, No. 487, vol. xxi., pp. 51–54).

THE PANORAM KODAK.

EVER since the year 1845, when Friedrich v. Martens, a copper-plate engraver living in Paris, constructed a camera with a rotating lens and arrangements for a curved plate for taking panoramic views, this method of working has engaged the attention of photographers. Martens's apparatus was designed for Daguerreotype plates, but the convenience of flexible films for such work must very soon have been appreciated, for in 1850 we find Fox Talbot taking the trouble to state that one of his sensitive papers was particularly well adapted for the purpose.

M. Garella, in 1857, employed a flat plate moving tangentially to the required curved surface as the camera rotated, and so obviated the necessity for the curving of the sensitive surface. Messrs. J. R. Johnson and J. A. Harrison worked on similar lines when they produced their "pantascopic camera" in 1862, and its subsequent improvements. These and several other inventors suffered from the disadvantage of having to use glass plates which, whether flat or curved, were awkward to manipulate, and if curved were costly and especially troublesome. Still, very excellent work was done with these apparatuses.

Modern panoramic cameras date, practically speaking, from the commercial preparation of flexible or film-supported sensitive surfaces. Commandant Moessard, in 1893, employed a curved film supported in a curved celluloid holder, while M. J. Damoizeau (1891), in his "cyclographe," and Colonel R. W. Stewart, R.E. (1893), in his "panoram," employed films in the most compact way possible, drawing the film from one roller to another as the camera rotates. Colonel Stewart's camera is very small for the size of picture that it takes, and will, if required, photograph the whole horizon at one operation. He constructed his apparatus for Eastman's films.

But all these cameras were, comparatively speaking, costly, heavy and complicated, being actuated by clockwork or the equivalent, and the later examples were designed to be applicable to photographic surveying. No one appears to have considered it possible to construct a panoramic camera that should be light and simple in construction, and so available for the ordinary tourist, until the enterprising firm of Kodak, Ltd., introduced their "panoram kodak." In this camera they have not only succeeded to this extent, but have provided what is commonly understood as a "kodak"—that is, a camera that may easily be held in the hand during the exposure. Its construction is very ingenious in its simplicity. During exposure, the only moving part is the lens, which swings on a vertical axis, and the only motive power is a spring. The spring acts on a lever, and as the arrangement is laterally symmetrical, the exposure can be started from the side that the lens happens to be pointing towards. There is no shutter as ordinarily understood, the lens revolves through a half circle, and at each end of its journey is accommodated in a little recess that prevents any light passing through it to the inside of the camera.

The sensitive surface is the roller film, which passes over guides that maintain it at the correct curvature. The picture produced is seven inches long and 2¼ inches high, and the definition is good over its whole length, showing that the difficulty of the correct adjustment of the swinging lens has been quite satisfactorily overcome. As already stated, the apparatus is of the simplest kind. The lens works always at the same aperture. It has two rates of movement, the equivalent of two speeds of a shutter, effected simply by putting the full or a partial tension on the spring. But long exposures can be given by just repeating the ordinary exposure as often as necessary, the camera, of course, being firmly supported. We have seen some excellent views of dark wooded scenery taken in this way.

It may be worth while to remind those who think that they would appreciate the possibility of getting views including a wide horizontal angle, that the perspective of the pictures produced by all such apparatus as that referred to is cylindric, and, being different from the more usual plane perspective of flat plates, requires different precautions on the part of the photographer to avoid unpleasant results. The chief of these precautions is due to the fact that horizontal lines that lie either above or below the axis of the lens are curved towards the axis. The horizon itself is, of course, never curved on the photograph if the camera is level, and the panoram is provided with a spirit level as a guide for this purpose. Speaking practically, the one kind of view to avoid may be exemplified by a long building photographed from a point approximately opposite to its centre, facing it, say, from the other side of the street. It is impossible by any means to set a satisfactory representation of such an object from such a position, but the temptation to make the attempt is greater with a panoramic camera than with the more usual apparatus.

Now that a panoramic camera suitable for ordinary purposes has been shown to be possible, we hope that the construction adopted will be applied to the production of other sizes and perhaps other qualities of apparatus.

C. J.

SOME RECENT ADVANCES IN BIOLOGICAL SCIENCE.[1]

A TIME-HONOURED distinction has been drawn between the so-called observational and the experimental sciences; and, pledged as we are to the former, we have to deal with those subjects which, in the hands of the immortal Darwin, have during the last forty years revolutionised all departments of science not wholly mathematical, for be it remembered that the formulation of the periodic law in chemistry is but that of an evolutionary hypothesis. So reactionary has been this influence upon thought and mental conduct, that it has rendered it impossible for us to think as did our forefathers, and has thereby increased our responsibility to our juniors and those who seek our guidance.

Never was progress more rapid than in these post-Darwinian days. Steady work in the discovery and classification of genera and species has proceeded all along the line, and with extending influence in the far East. Some idea of what is now taking place in our chosen field may be formed from the fact that, since the adoption of western methods by the Japanese, we have not only to record zoological discoveries of first-rate order, due to the fact that they alone possess the material upon which they are based, but to their lasting credit be it said that they have put us right on fundamentals upon which we have for generations imagined we knew all. To wit, a young Japanese, Hirota by name, alas, now dead! availing himself of the discovery by his teacher of a peculiar condition of the egg-membranes in the native tortoises, was led to argue that since these creatures and birds are not so very distantly related, the like might be forthcoming in them; and turning to the common chick—the bird most ready to hand—he succeeded in proving not only the existence of the condition suspected, but that we in the West, with our boasted methods and resources, by error of orientation, contenting ourselves with the mere examination of parts, instead of the whole object, have gone wrong on an elementary and most important detail.

One immediate effect of the demonstration of the truth of evolution, now historically established, has been the substitution for the old-fashioned and merely tabular classifications of animate beings, of linear arrangements and phylogenetic trees. To those of the Hæckelian school, fired by an energy of enthusiasm, it appeared easy to locate every known creature to its proper place in the series; but while these persons did good by the stimulating influence of their work, it is needless to say that the hasty construction of such schemes must be fraught with error. So colossal a task is not to be achieved in a lifetime, and it too soon became evident that these fantastic expressions of supposed facts, like all classificatory formulæ, had to give way under the growth of knowledge, until now the time has come when our classifications of animals, which, be it said, are at best but the tentative expression of our ideas, are being based, not on the mere characters of the exterior, or of a single series of parts, but on the sum total of the maximum number of characters observable. Where we once thought we detected relationships, we now know we were often being misled, and the old-time supposition that mere community of structure is necessarily an index of community of origin has gone to the wall.

The past three decades will be ever memorable in the history of biology as that of what may be termed the embryological reaction, prompted by the thought that the clue to the origin of an animal in the remote past lies in the study of its development from the egg, believed to recapitulate the history of its race. Great, however, has been the disappointment in this respect, it having been discovered in many cases that the animate being,

[1] Abridged report of the Presidential Address, delivered by Prof. G. B. Howes, F.R.S., before the South-Eastern Union of Scientific Societies, at their Fifth Annual Congress, held in Brighton.

during its development, is so liable to adaptive change of but passing significance, that it becomes difficult to distinguish between this and the historic record originally believed to be passed through. But, that notwithstanding, upon data of this order many of our recent conceptions of the origin and succession of animal forms have been built up; and it is clear that if, on the basis of such facts, we attempt to deduce those generalised statements we term "laws," the test of our accuracy lies in appeal to the fossiliferous strata, in which we ought to find evidence of their presumed operation in the past. Here I am led to emphasise the importance of the study of palæontology, and, as bearing on the argument deduced from that of development, a striking outcome of recent palæontological investigation has been the unearthing, in the United States of America, of perfectly preserved remains of the Trilobites, the oldest and most primitive of all Crustacean forms. These creatures are now proved to have been possessed of but one pair of antennæ, there being two pairs present in every ordinary later member of the Crustacean class. It so happens, however, that this is the case for the adults only, and that the presence of but a single pair is characteristic of the larval stage through which all freely developed Crustacea pass, and, from what is now known of the details of the appendages of these Trilobites and the said Crustacean larvæ, there can be no doubt that in this particular class of animals the larva is realistic in its characters of the remote ancestor from which, in past ages, its members have been derived.

Other memorable instances have come to hand in the study of the palæontological record, which have profoundly modified our conceptions of the succession and primary relationships of animal forms. For example, evidence is now accumulating that in the case of birds the remote ancestors were of a more primitive reptilian stock than has been until recently supposed. Again, those structural features in respect to which the living Batrachia simplify the reptilian type are now coming to be recognised as largely due to retrogressive change, and we are beginning to see that both these classes of animals in all probability converge towards an assemblage of palæozoic forms, combining the characters of the two as to-day represented, and that the older naturalists, in classifying the cold-blooded terrestrial vertebrata together, were perhaps not so far out as we have been prone to think. A wonderful chapter has quite lately been added to the history of the horse, by the discovery in South America of an equine animal which possessed the single toe and other features familiar in it. The race to which it belonged has apparently become extinct only in quite recent times, and when we picture to ourselves the course of events to which it points, we conclude that in early Tertiary times the ancestors of the horse tribe, arising in Central America, migrated into the Old World, on one hand, and into South America on the other; and in each, by independent but parallel differentiation, gave rise to an essentially similar definitive form. Survival of this in the Old World alone has resulted in the horses of to-day, those now living in America having been secondarily imported by man.

The case in some respects recalls that of the pig tribe, except that, with this, migration in opposite directions has been accompanied by diversity of modification. Originating in early Tertiary times in Central North America, their ancestors migrated on one hand into the Old World, and by complication of their teeth gave rise to the swine and hogs of later times, while on the other hand, passing into the southern parts of America, they by numerical reduction of their teeth and toes gave rise to the peccaries of to-day.

Taken in conjunction with the now well-recognised fact that certain animals which in life and in all superficial features resemble each other can be proved on examination of more deeply-seated characters to be genetically distinct, this consideration raises the question of the importance of what is known in nature as the phenomenon of "Convergence." We now know of creatures externally almost indistinguishable from slugs which have the internal anatomy of snails and of slugs occurring independently in different parts of the world which exhibit a repetitional similarity of relationship to the snails of their respective areas; and we have long been familiar with a Crustacean—the "King Crab"—living on the opposite shores of the North Pacific, which, in respect to the segmentation of its body and the number and characters of its limbs more especially, conforms to the Scorpionid type. Numerous other instances might be cited, but these are sufficient, and the question for consideration is, how far such superficial resemblances, in that they have led to the association of forms in which they occur in a common classification, are trustworthy as criteria of affinity. The case for the King Crab and the Scorpion is one of long standing, and there is reason to believe it is still open to doubt. In all groups of Arthropods, to which both creatures belong, we meet with forms in which the familiar free body-rings or "segments" are for the greater part united, and others in which they are free, and there can be no doubt that the degree of union of these, which takes place in definite antero-posterior succession, is a sure index of "highness" and "lowness" in a given series—those in which few segments unite being low, those in which many unite, high. To this process of fusion of body-segments our American *confrères* apply the expressive term "cephalisation," and, when this test is applied to the two groups to which the animals in question belong, it is found that, in respect to it and certain correlated modifications, they each stand at the summit of their respective series—*i.e.*, that there are, among the "spiders," forms which, at least as regards cephalisation, simplify the Scorpionid type along lines parallel with those in which the so-called Eurypterids of the past, in this and other respects, simplify the King Crab type; and when, further, it is found that among the fossil Scorpions known there are indications of simplification of exactly the order the facts would lead us to suspect, it follows that King Crab and Scorpion of to-day each hark back to a distinct and independent assemblage of forms. With this, the association together of the culminating types, as in most of our current classifications, becomes dangerous, if not misleading; and we are brought to the realisation of the fact that mere community of adult structure does not necessarily imply community of origin, and that by a parallelism of modification two creatures of diverse ancestry, in adaptation to the conditions of life, may, independently, and by "convergence," assume a similar form.

The approximate resemblance between the crowns of the teeth of the horse and ox is a familiar example, and we have evidence that in this way certain types of teeth represented among the living mammals, by which these are still classified, have been anticipated by totally different groups in past periods of time; and if we are to trust recent research, teeth already modified along lines anticipatory of the carnivorous and herbivorous types of to-day co-existed in an assemblage of supposed cretaceous mammals of South America whose affinities are as yet not fully established.

The extent of the operation of "Convergence" in nature's work is but now becoming recognised, and there is proof to hand that many of our time-honoured classificatory systems are erroneous, by failure of its appreciation in the past. Impressed by this, it behoves us to reflect to what an extent nature's plans, so to speak, have, in the history of organic evolution, as in that of civilisation, repeated themselves, she being apparently intent on a recurrent diversity of differentiation, for some purpose associated with the balance of life we do not understand, as in the fact that when, in Mesozoic times, she had but the reptiles upon which to operate, she produced terrestrial, aquatic and flying forms, just as, in later periods, she has produced them with the mammals, which replaced these in order of time.

Again, with the development of the Darwinian doctrines, there early arose the realisation that, on the principle of descent with modification, the summary appearance of organs having no existence in near allies, either during the development of certain species or on the assumption of the adult state, presented a difficulty which even Darwin himself, ever more justly critical of his own work than many of his would-be opponents, clearly admitted. The independent appearance of luminous organs and those of electrical discharge in remotely related groups of fishes are ideal cases, at first sight calculated to break the back of the rigid Darwinian. Some thirteen years ago, Dr. Anton Dohrn, of Naples, and the late Prof. Kleinenberg, of Messina, formulated the doctrine of "Substitution of Organs," which provides that under varying conditions of life, and at different periods of development, sets of organs may replace others, to the better fulfilment of the life of the individual or race. To apply this to the case of the organs of electrical discharge in fishes in no way closely related, let it be said that our commonest rays and skates are possessed of such an organ, located in the tail. The peculiar feature of these fishes is the usurpation by their expanded side-fins of the propelling action, which, in ordinary fishes, is performed by the tail. What more

reasonable, therefore, when we know these rays and skates to have been derived from heavy-tailed shark-like ancestors with small side-fins, than the question how far conversion of the tail into an organ of electrical discharge may not have been the outcome of the taking-on by the side-fins of the swimming function? The answer to this is convincing and complete, for we find among the tropical and more distant allies of these rays, that the tail may become by elongation in one species a delicate trailing whip-lash; by abbreviation in another a mere vestigial stump, or by the addition of spines in yet another a formidable weapon of offence. Clearly, rid of the propelling function, it has become free to modify its ways, and the conversion into an organ of electrical discharge is found to be but one of a series of independent adaptations by "substitution."

Other and more beautiful examples of the working of this law might be cited, such, for example, as that of the provision for "casting" the tail, so well known among living lizards; but sufficient is before us to show in what manner the advance of knowledge dispels our difficulties, and that the stumbling-block of one generation may become the stepping-stone of the next.

If evolution—defined as the law of descent with modification, and involving the process of progressive advancement and passage with time from the simple to the more complex—is all sufficient to explain the existence and succession of the diverse forms of life, it might well appear that the conditions of modification are more complex and less regular than would have been expected; and we are, therefore, led to inquire in what the determining cause of modification and hereditary tendency may perchance consist. Looking back on the history of biology, three great names stand out above all others as those of the pioneers in its turning-points, Linné, Cuvier and Darwin. Linné taught us how to name and describe the objects in nature; Cuvier impressed upon us the fact that unity of structure underlies the great diversity in superficial form; Darwin, for the first time, furnished the clue to this unity, on the lines to which I have already referred, and showed us that vital phenomena are attributable to the working of a fixed set of laws.

It may be said of all living things that, so far as their bodies consist of a mass of living substance, which we term protoplasm, they are structurally identical. In seeking to classify them, be they plants or animals, the sharpest working distinction to be drawn is between those which consist of one structural unit or are unicellular, and those which consist of an aggregate of units or are multicellular—hence our terms Protozoa and Metazoa, Protophyta and Metaphyta, or collectively Monoplastids and Polyplastids, the term "plastid" being sometimes substituted for "cell." While the monoplastids, mostly though by no means all visible only under a lens, consist each of but one cell, one structural unit, of the order of those which in the aggregate compose the body of the polyplastid, there is no fundamental difference recognisable in the manner and extent to which multi- and uni-cellular beings stand related to the universe at large. Both are motile and sensitive; both produce waste, by processes which unchecked lead to decomposition and death; both stand, therefore, in need of recomposition and must be nourished; and both are loyal to the divine command to increase and multiply. It is concerning this reproductive process that the post-Darwinian period has witnessed an altogether unparalleled activity, in the attempt to get at the essence and to unravel the mystery of hereditary influence. The mental giant who has led the way is Prof. Weismann, of the University of Freiburg, in Breisgau. His whole series of doctrines find their focus in three epoch-marking addresses, which he delivered in 1881–1883 before the Association of German Naturalists and his University, entitled "On the Duration of Life," "On Heredity" and "On Life and Death." He took his stand upon the well-known fact that whereas reproduction of the unicellular organism is by a simple process of fission, the individual dividing into two without loss of substance, and becoming at once parent and offspring—in the multicellular organism the reproductive act involves only an insignificant portion of the body, and is sooner or later accompanied by the death of that which remains, and a consequent loss of substance. From this he argued that inasmuch as it is conceivable that the fissiparous process may go on indefinitely, the Protozoan of to-day may have arisen by repeated and prolonged fissiparous activity from that of long passed ages, and that the organism, never having suffered a loss of substance, may be immortal. Founding, in this way, his doctrine of the "Immortality of the Protozoa," he was led, by realisation that that portion of the body of the multicellular organism which fulfils the reproductive function passes to its share in the formation of a new individual a living element, to distinguish between it, the "germ-plasma" which never dies, and the rest of the body or "somatoplasma," which is lost by decomposition and death, and he in this way sought to extend the conception of immortality to the reproductive elements of the higher organisms.

This marvellous generalisation—prettier far than poetry—created in the early "nineties" a veritable furore; and it furnishes us with material for reflection and mental consideration of an altogether unique order. So profound, however, was its effect upon contemporary science and thought, that under its influence there arose a horde of eager investigators, intent on its development and the search for the seat of primary hereditary influence. The literature and vexed controversies which have in consequence arisen are now voluminous, and Weismann and his followers, eager to push forward, have pressed theory upon theory, often with contradictory effect. His whole series of observations, however, focus in the afore-named great generalisation, and, as for alleged contradiction, I can only regard it as due to the influence of his friends, who, eager for his advance, and perhaps, in the case of some, for association with his work, forced him to extremes which he would never have contemplated had he been left alone.

As might be supposed, the conception of the immortality of protoplasm has not passed unchallenged. Maupas, an acute French investigator, has discovered of the familiar "Bell Animalcules," that prolonged fissiparous reproduction is accompanied by progressive diminution in stature, leadin , if unchecked, to senility and decay; and, having determined by observation the number of generations in which this veritable extinction may be brought about, he has succeeded in proving that, by means of a conjugative process, involving a blending of two individuals, its effects are overcome. To what this remarkable discovery may ultimately lead we know not, but it so happens that, whether the conception of immortality be right or wrong, it arose in the minds of trained naturalists long before Weismann's time. He himself starts with a quotation from Johannes Müller, the founder of comparative anatomy, to the effect that "organic bodies are perishable, and that, while life maintains the appearance of immortality, in the constant succession of similar individuals, the individuals themselves pass away." And similarly, R. Owen, in two great lectures on "Parthenogenesis," delivered before the Royal College of Surgeons, in 1849, came nearer the mark, with the astounding paragraphs:—

"Not all the progeny of the primary germ-cell are required for the formation of the body of all animals; certain of the derivative germ-cells may remain unchanged, and become included in that body which has been composed of their metamorphosed and diversely combined or confluent brethren. So included, any derivative germ-cell . . . . may commence and repeat the same processes of growth and imbibition, and of propagation by spontaneous fission, as those to which itself owed its origin, followed by metamorphoses and combinations of the germ-masses so produced, which concur to the development of another individual, and this may be, or may not be, like that individual in which the secondary germ-cell or germ-mass was included."

And, concerning the conception of immortality of the Protozoa, he also wrote:—

"It is by no means easy to find a name for the relation in which the fissiparous monad stands to the two monads between which it has been equally divided. A parent retains its individuality distinct from its progeny; but the monad has become a part, and indeed the chief part, of the two that have resulted from its spontaneous fission. Both separate moieties are, in an equal degree, the same individual as the whole from which they proceeded; and in an infinitesimal, though conceivable, degree, the actual monad is the same individual as the first created one, from which it may have proceeded by an uninterrupted succession of spontaneous fissions, and in that degree it may be viewed as one of the oldest known individuals in creation, the individual being never wholly or in part deceased."

Not that this in any way detracts from the merits of Weismann's labours! On the contrary, to him is due the credit of having put the vitally important topic which now concerns us on a scientifically sound and workable basis—an achievement of which he may well be proud.

It being evident that the unicellular and multicellular organisms stand alike responsible to the universe at large concerning

their functional activities, we are led to inquire in what way the localisation of these in the higher and compound forms may have come about. "Differentiation of labour" is the popular explanation, and one is prone to ask whether the structural or the functional differentiation was first achieved. It has generally been taught in the past that the structural preceded the functional, but we are now coming to doubt this long-cherished conclusion, in evidence of the fact that nature will, with equal facility, effect corresponding differentiation for the fulfilment of the same end, in either the whole body of a unicellular organism or a localised part of a multicellular one—in either a single cell or a cell-aggregate—as, for example, in the formation of what are known as the ciliated membranellæ of the Infusor *Stentor*, and the so-called corner-cells of the Mollusc *Cyclas*. Differentiation depends, not on the interaction of cells, but upon the elementary structure and potentialities of protoplasm, or, as Prof. C. O. Whitman, of Chicago, has expressed it, "organism precedes cell-formation."

If this be so, there is raised the question how far the idea, developed during the past two decades, that the animate being is a mere blind automaton, and its actions but complicated functions of a chemico-physical order such as we deduce from the study of the inanimate, is correct, and we are prone to inquire if the structural units of the animal body are, so to speak, bricks set to a mathematical relationship, controlled by laws of pressure, or living units, capable of working to their own ends, and defying mechanical conditions such as apply to the inanimate.

It has long been said of us devotees to the observational branches of science that our methods are inaccurate by lack of qualitative treatment, and the distinction has been drawn between ours, the so-called "inexact," and the mathematical or "exact" sciences. On this basis there are now being pushed forward attempts to apply statistical, experimental and mathematical tests to the study of vital phenomena. All honour to those who are making them, for it is certain there are phases of life capable of mathematical treatment, but the mystery of life can never be thus solved; and, concerning the objection to the observational method, I would remark that if by that we are to understand observation, with confirmation and generalisation, and rejection of the non-confirmable, our non-mathematical procedure is scientific. Huxley has long ago said of mathematics that what you get out of the machine depends entirely upon what you put into it.

Ten years ago, any one asked to define the nature of the primitive organism from which all organic beings are descended, having regard to then known chemical phenomena of life, would most certainly have argued in favour of a green-plant, or of some organism capable of decomposing CO_2 under the action of sunlight, and of raising inorganic substances to an organic level, thereby rendering them fit for animal food. We now know of the existence of lowly organisms capable of decomposing CO_2 in the absence of chlorophyll. The ploughing in of the roots of certain leguminous plants, in which our German cousins have been for years ahead of us, is now well known to be associated with the presence of fungi, capable of assimilating the nitrogen of the soil. In the nitrifying bacteria, we are now familiar with organisms by whose aid ammonia becomes the origin of nitrates and nitrites, and there are others which, by a process of denitrification, effect the reduction of these, with liberation of free nitrogen. And startling indeed is the knowledge that there exist in certain seas, and, it may be, near our very doors, bacteria which possess the marvellous power of decomposing sulphates, and of living in an atmosphere of sulphuretted hydrogen. The discovery that certain lowly fungi are so sensitive to chemical change in their nutritive media, that the presence of one part in 50,000 of zinc chloride will act as a powerful stimulus, and produce a growth some 700 times its own initial weight, and that one part in 1,600,000 of silver nitrate is abruptly fatal to it, is simply astounding.

Turning to the animal, we find that whereas in the case of the hot-blooded rabbit the weight of oxygen per hour sufficient for the maintenance of life is as 2·284, in the case of the cold-blooded American turtle it falls to 0·088. With the animal, as with the plant, so sensitive are the parts of the body to variation in chemical composition of fluids with which they may be brought into contact, that, under conditions of experiment, it has been found that the heart of a frog, of which the beat has been lessened or arrested by treatment with salt-solution or distilled water, may be revived by the accession of one part in 10,000 of calcium carbonate.

What all this means, regarding the processes involved in the mystery of life, and in what direction it is leading us, the future can alone sufficiently show. One thing is certain, that since living matter in all its forms is constantly undergoing waste and disintegration by oxidation, life is possible only under a penalty of death, and we are prone to inquire if this is a mere chance circumstance or a necessity to some beneficent end. We know that in the order of evolution the simpler forms of plants and animals have, by combination and advancement, given rise to the more complex, and it is clear that if this process were to go on indefinitely, a time might come at which all the simpler forms would be used up, and life would cease. The breaking up of the complex forms and the dissociation of their elements, however, results in the return to mother earth of the raw material of which they are composed, and thereby renders possible the repetition of the cycle, and from this it follows that the destruction of the individual may have been really a necessity, in order that others might live.

In this consideration we are once more brought into touch with inorganic nature, and it is a remarkable fact that the very chemical elements which enter into the composition of the simplest protoplasmic structures are precisely those contributing to the formation of the simplest of chemical substances, so far, at any rate, as hydrogen, oxygen, nitrogen, sodium, calcium, magnesium and iron are concerned. My friend and colleague, Sir Norman Lockyer, has recently emphasised this consideration, and, with a boldness worthy his great reputation, has dared to discuss the significance of the facts. The spectroscopic analysis of the hotter stars has revealed to him the truth that their simple chemical constitution is explained by the fact that the final products of dissociation by heat are the earliest chemical forms. From this he deduces the conclusion that with the heavenly bodies, as with the organic world, the simplest forms appeared first, and that the dissociation stages of the former, as of the latter, reveal to us the forms the coming together of which has produced the thing dissociated or broken up. Passing from the hottest to the cooler stars, he argues that, like the various geologic strata, these bring before us a progression of new forms of increasing complexity in an organised sequence, and, developing this pregnant line of thought, he reverts to the uniform simplicity in chemical constitution of the earliest inorganic and the primitive organic forms, and deduces the belief that "the first organic life was an interaction, somehow or other, between the undoubted earliest chemical forms." It is a far cry from the primitive monad to the hottest star, but so convinced is Sir Norman Lockyer of the analogy between the methods of organic and inorganic evolution, that he has used the latter term as the title of his book, which I can strongly recommend to your earnest consideration. We advance by facts, we live by ideas, and if Sir Norman Lockyer's fascinating theory does no more than set the trained mind to work and arouse interest in the topics with which it deals, it will have served its purpose.

To turn now to the physical properties of living matter. Concerning the eye, it may be said that in the contraction of its retinal pigment by a vital act in definite response to the rays of the spectrum, and in the falling to a focus, within the substance of the crystalline lens, of the inverted image formed by that, it is neither constructed nor behaving in the manner of the inanimate photographer's camera, with which it has been *ad nauseam* compared! Again, the discovery in recent years that whereas, during life, the gaseous diffusion of respiration does not take place in strict conformity with the laws applying to inanimate membranes, it does so after death, with that of the changes and processes undergone by the food in its passage through the intestinal wall, now proved to be of no mere mechanical order, testify to the conclusion that the moment you bring the conditions and arguments deduced from the study of the inanimate to bear upon what may be expressively termed the animate organic membrane, they either do not apply or are set at defiance.

Many other examples might be cited. We are getting back to a conception of a "vital force," not of the order of the ancients—a "Psyche"—a mysterious controlling influence beyond our ken, but one which we may term a *Neo-Vitalism*, which teaches us that although organic matter is in its manifestations chemical and physical and the basis of life is associated with chemical and physical processes, the physics and chemistry are not those of the inanimate as at present understood, and gives us hope of its discovery if we will but persevere.

Finally, as to the charge of inexactitude. It is one of the

blessed aspects of the study of animate nature that there may be the alternative interpretation. Work at a problem long as you will, you will find that when you flatter yourself you have obtained the clue to its significance it will often happen that it is just that which you have missed.

Call it ambiguity if you will; it is primarily due to the structural and functional complexity of living matter, and there lies in it, to my mind, the greatest charm of our science, in that it appeals to the imagination, and therein arouses one of the highest of the intellectual faculties. We work in hope, content to investigate the reason of phenomena, but the nature of things will be ever beyond our grasp.

As contributing to the advancement of knowledge, and to a fuller understanding of the phenomena which underlie the operations of nature, the topics to which I have drawn attention are among the most important in the recent progress of science —the most revolutionary results of patient, persistent inquiry. In their definitive form, the so-called "laws of nature" are but generalised statements of fact, and, so far as we are individually concerned, I would remind you that, since we are but members of the great animal subkingdom, dependent, with the probable millions of species which compose it, upon a common set of conditions in our relations to the universe at large, it is impossible, if we would know and appreciate our position in the world, to present a deaf ear to their teaching. It behoves us not only to ponder them on our own account, but to see to it that, as time progresses, those committed to our charge are so brought up as to be not wholly ignorant of them.

And this brings me to the concluding portion of my address.

As members of local committees and scientific societies, we are pledged to the task of what is known as popular education, and its correlate the "popularisation of science." Exactly what this hackneyed expression may be taken to imply I have never yet discovered, and, speaking for myself, I regard it as erroneous. Science cannot be popularised, and any work to-day worthy the name of scientific must be technical. To popularise science is an impossibility, but to popularise the results of it is quite another thing.
